#### Abstract

Conventional techniques to cluster gene expression time course data have either ignored the time aspect, by treating time points as independent, or have used parametric models where the model complexity has to be fixed beforehand. In this thesis, we have applied a non-parametric version of the traditional hidden Markov model (HMM), called the hierarchical Dirichlet process hidden Markov model (HDP-HMM), to the task of clustering gene expression time course data. The HDP-HMM is an instantiation of an HMM in the hierarchical Dirichlet process (HDP) framework of Teh et al. (2004), in which we place a non-parametric prior on the number of hidden states of an HMM that allows for a countably infinite number of hidden states, and hence overcomes the issue of fixing model complexity. At the same time, by having a Dirichlet process in a hierarchical framework we let the same countably infinite set of "next states" in the Markov chain of the HMM be shared without constraining the flexible architecture of the model. We describe the algorithm in detail and compare the results obtained by our method with those obtained from traditional methods on two popular datasets - Iyer et al. (1999) and Cho et al. (1998). We show that a nonparametric hierarchical model such as ours can solve complex clustering tasks effectively without having to fix the model complexity beforehand and at the same time avoids overfitting.

## Acknowledgements

I would like to thank my advisor, Matthew J. Beal, for his support and guidance. Two years ago when I started my Masters program, I had no idea it would turn out this way. I've learnt a lot in the area of Machine Learning and it has been a wonderful experience working with him.

I would also like to thank Dr. Aidong Zhang for her inputs in the Bioinformatics course. That was my first introduction to bioinformatics, and has helped a lot me in this thesis.

I would like to acknowledge my colleagues - Rahul Krishna, whose notes came in handy in the description of Dirichlet Processes and Hierarchical Dirichlet Processes. And Shravya Shetty for proof reading this manuscript.

## Chapter 1

## Introduction

Genes are the units of heredity in living organisms. They are encoded in the organism's genetic material, and control the physical development and behavior of the organism. During reproduction, the genetic material is passed on from the parent(s) to the offspring. Genes encode the information necessary to construct the chemicals (proteins etc.) needed for the organism to function.

Following the discovery that Deoxyribonucleic acid (DNA) is the genetic material, the common usage of the word 'gene' has increasingly reflected its meaning in molecular biology, namely the segments of DNA which cells transcribe into Ribonucleic acid (RNA) and translate into proteins. The Sequence Ontology project defines a gene as: "A locatable region of genomic sequence, corresponding to a unit of inheritance, which is associated with regulatory regions, transcribed regions and/or other functional sequence regions".

### 1.1 Gene expression

Gene expression, often simply called expression, is the process by which a gene's DNA sequence is converted into the structures and functions of a cell.

Gene expression is a multi-step process that begins with transcription of DNA, which genes are made of, into messenger RNA. It is then followed by post-transcriptional modification and translation into a gene product, followed by folding, post-translational modification and targeting.

The amount of protein that a cell expresses depends on the tissue, the developmental stage of
the organism and the metabolic or physiologic state of the cell.

### 1.1.1 Microarrays

Microarray refers to both the process and the technology used to measure the expression of particular genes. Microarray technology or more specifically DNA microarray technology provides a rough measure of the cellular concentration of different messenger RNAs (mRNA).

A DNA microarray (also known as a gene chip, or bio chip, or DNA chip) is a collection of microscopic DNA spots attached to a solid surface, such as glass, plastic or silicon chip forming an array for the purpose of monitoring of expression levels.

The affixed DNA segments are known as probes, thousands of which can be used in a single DNA microarray. Measuring gene expression using microarrays is relevant to many areas of biology and medicine, such as studying treatments, disease, and developmental stages. For example, microarrays can be used to identify disease genes by comparing gene expression in disease and normal cells.

DNA microarrays can be used to detect RNAs that may or may not be translated into active proteins. Scientists refer to this kind of analysis as "expression analysis" or expression profiling. Since there can be tens of thousands of distinct reporters on an array, each microarray experiment can accomplish the equivalent of a number of genetic tests in parallel. Arrays have therefore dramatically accelerated many types of investigations.

Depending upon the kind of immobilized sample used construct arrays and the information fetched, the microarray experiments can be categorized in three ways:

1. Microarray expression analysis: In this experimental setup, the complimentary DNA (cDNA) derived from the mRNA of known genes is immobilized. The sample has genes from both the normal as well as the diseased tissues. Spots with more intensity are obtained for diseased tissue gene if the gene is over expressed in the diseased condition. This expression pattern is then compared to the expression pattern of a gene responsible for a disease.
2. Microarray for mutation analysis: For this analysis, the researchers use genomic DNA (gDNA). The genes might differ from each other by as less as a single nucleotide base. A single base difference between two sequences is known as Single Nucleotide Polymorphism (SNP).

Figure 1.1: A typical dual-color microarray used in expression analysis
3. Comparative Genomic Hybridization: is used for the identification in the increase or decrease of the important chromosomal fragments harboring genes involved in a disease.

A few applications of microarrays are:

1. Gene discovery: Microarray experiments helps in the identification of new genes, know about their functioning and expression levels under different conditions.
2. Disease diagnosis: Microarray technology helps researchers learn more about different diseases such as heart diseases, mental illness, infectious disease and especially the study of cancer. Until recently, different types of cancer have been classified on the basis of the organs in which the tumors develop. Now, with the evolution of microarray technology, it will be possible for the researchers to further classify the types of cancer on the basis of the patterns of gene activity in the tumor cells. This will tremendously help the pharmaceutical community to develop more effective drugs as the treatment strategies will be targeted directly to the specific type of cancer.
3. Drug discovery: Microarray has extensive application in Pharmacogenomics. Pharmacogenomics is the study of correlations between therapeutic responses to drugs and the genetic profiles of the patients. Comparative analysis of the genes from a diseased and a normal cell
will help the identification of the biochemical constitution of the proteins synthesized by the diseased genes. The researchers can use this information to synthesize drugs which combat with these proteins and reduce their effect.
4. Toxicological research: Toxicogenomics establishes correlation between responses to toxicants and the changes in the genetic profiles of the cells exposed to such toxicants.

### 1.1.2 Time series data

Time series data for gene expression is obtained when expression values are read off at various time points during a single experiment. Oftentimes many experiments are run in parallel and stopped for measurement one by one at allotted time points; this is particularly true for mammalian experiments where DNA measurement requires the sacrifice of the subject. While this procedure does not produce a pure single time course, and instead one made from many terminating time courses, biologists and bioinformaticians do consider it viable time course data.. Expression values can be read off at equal or unequal intervals of time. The primary goal of collecting time series data is to gain insight into understanding genetic regulatory networks (GRN). A GRN is a collection of DNA segments in a cell which interact with each other and with other substances in the cell, thereby governing the rates at which genes in the network are transcribed into mRNA.

Regulation of gene expression (gene regulation) is the cellular control of the amount and timing of appearance (induction) of the functional product of a gene. Although a functional gene product may be an RNA or a protein, the majority of the known mechanisms regulate the expression of protein coding genes. Any step of gene expression may be modulated, from the DNA-RNA transcription step to post-translational modification of a protein. Gene regulation gives the cell control over structure and function, and is the basis for cellular differentiation, morphogenesis and the versatility and adaptability of any organism.

Two genes are said to co-express when they have similar expression patterns, and they are said to co-regulate when they are regulated by common transcription factors. Viewed from the co-expression point of view, co-regulation would lead to similar expression patterns over time as the genes are regulated by common transcription factors. Hence, similar expression pattern over
time could give important information regarding the underlying genetic regulatory networks.

### 1.2 Clustering genes

There are about 25,000 genes in a human being, and only a few of them have been completely analyzed, annotated and well understood. Understanding genes and their functionality remains a prime objective of human genome researchers.

Why do we need to understand genes?

1. Disease diagnosis: Understanding genes can help in understanding the causes of diseases at the cellular level. For example, cancer classification can be done based on patterns of gene activity in the tumor cells.
2. Gene discovery: Understanding genes can aid in understanding the functionality of unknown genes. As mentioned earlier, very few genes have been completely understood, so discovery of new genes is an important step in understanding and building a comprehensive gene database.
3. Gene therapy: is the insertion of genes into an individual's cells and tissues to treat a disease, and hereditary diseases in particular. Gene therapy is still in its infancy, and a better understanding of genes would help devising effective therapies.
4. Gene expression analysis of one gene at a time has provided a wealth of biological insight, however analysis at a genome level is yet to be carried out.

### 1.2.1 The task

Given that we have gene expression time-course data, our task is to cluster them into groups of genes with similar expression patterns over time. Such a task can be unsupervised - in which case we have no information regarding any of the genes being analyzed, or it can be supervised - wherein genes are clustered based on their similarity to known genes. We undertake the former task, as it is can be applied even in the absence of labeled data, and in many a case is an important step in the latter task.

### 1.2.2 Challenges

Clustering gene expression time-course data is not a trivial task. Not only does it involve devising a measure of similarity for genes, but also involves the tricky problem of identifying the number of true clusters. Some of the problems that need to be taken care of in devising a method to cluster time series data are:

1. Due to the high throughput of microarrays, the levels of error and noise in the measurements are high.
2. Data is often incomplete with many missing values.
3. Unequal time interval between successive time points.
4. Genes can be involved in several pathways and have multiple functions depending on specifics of the cell's environment. Hence, groups of genes defined according to similarity of function or regulation of a gene are not disjoint in general.

In this chapter we have described some of the concepts involved in gene expression analysis like gene expression, microarrays, gene regulation, time-course data etc.. We have also defined the task of clustering gene expression time-course data. The rest of the thesis reviews some of the methods researchers have adopted to solve this task, and our approach towards the problem.

## Chapter 2

## Literature Review

### 2.1 Clustering

Clustering is the partitioning of a data set into (disjoint) subsets, called clusters, so that the data in each subset share some common trait - often proximity according to some well-defined distance measure. Clustering is mostly seen as an unsupervised problem - where in no labeled data is available. Based on the technique used to create clusters and the proximity measure, one can have many clustering methods.

### 2.1.1 Clustering methodologies

Clustering methods broadly fall into one of the following categories:

1. Partition based clustering: In a partition based clustering algorithm, data is divided into mutually exclusive groups so as to optimize a certain cost function. An example of cost function could be sum of distances of all points from their respective cluster centroids. Such a cost function aims to produce clusters which are tight and compact, and this clustering method is called the $k$-means clustering. Partition based clustering generally involve reassignment of data points to clusters in successive iterations to obtain a locally optimal value for the cost function.
2. Hierarchical clustering: algorithms find successive clusters using previously established clus-
ters (unlike partition based algorithms which determine all clusters at once). Hierarchical algorithms can be agglomerative (bottom-up) or divisive (top-down). Agglomerative algorithms begin with each element as a separate cluster and merge them in successively larger clusters. Divisive algorithms begin with the whole set and proceed to divide it into successively smaller clusters.
3. Density based clustering: involves the density-based notion (not to be confused with probability density) of a cluster. A cluster is defined as a maximal set of density-connected points. Density Based Clustering starts by estimating the density for each point in order to identify core, border and noise points. A core point is referred to as a point whose density is greater than a user-defined threshold. Similarly, a noise point is referred to as a point whose density is less than a user-defined threshold. Noise points are usually discarded in the clustering process. A non-core, non-noise point is considered as a border point. Hence, clusters can be defined as dense regions (i.e. a set of core points), and each dense region is separated from one another by low density regions (i.e. a set of border points).

An increasingly popular approach to similarity based clustering (and segmentation) is by spectral methods. These methods use eigenvalues and eigenvectors of a matrix constructed from the pairwise similarity function. Given a set of data points, the similarity matrix may be defined as a matrix $S$, where $S_{i j}$ represents a measure of the similarity between point $i$ and $j$. Spectral clustering techniques make use of the spectrum of the similarity matrix of the data to cluster the points.

### 2.1.2 Cluster validation

One of the most important issues in cluster analysis is the evaluation of clustering results to find the partitioning that best fits the underlying data. By validating clusters obtained by a clustering algorithm, we assess the quality and reliability of clustering result. Some of the reasons why we require validation are:

1. To check if clustering is formed by chance. Clustering by chance is more severe when the number of clusters/classes is small.
2. To compare different clustering algorithms.
3. To choose clustering parameters. Typically, in an unsupervised learning environment, the number of classes/labels is not known beforehand, hence this parameter is provided as an input to the clustering algorithm. Validation can help fixing this parameter. Some of the other parameters that clustering algorithms require are density and radius (in density based clustering algorithms).
4. When the data is high dimensional, effective visualization of clustering result is often difficult and may not be the best method to evaluate the quality of the clustering. Hence, a more objective approach to validate clusters is preferable.

Cluster validation is usually done by computation of indices. Indices are scores which signify the quality of clustering. There are 2 kinds of indices - external and internal. External indices are obtained by comparison of clustering result with the ground truth or some pre-defined partition of the data which reflects our intuition about the clusters, whereas internal indices do not depend on any external reference and use only the data to validate clusters.

## External indices

As mentioned before, external indices are computed by comparison with ground truth. Let $N$ be the number of data points. Let $P^{\prime}=\left\{P_{1}, \ldots, P_{m}\right\}$ be the ground truth clusters. Let $C^{\prime}=\left\{C_{1}, \ldots, C_{n}\right\}$ be the clustering obtained by a clustering algorithm. We define two $\mathrm{N} \times \mathrm{N}$ 'incidence' matrices ( P and C), where the rows and columns both correspond to data points, as follows - $P_{i j}=1$, if both the $i^{\text {th }}$ point and the $j^{\text {th }}$ point belong to same cluster in $P^{\prime} ; 0$ otherwise. And, $C_{i j}=1$, if both the $i^{\text {th }}$ point and the $j^{\text {th }}$ point belong to same cluster in $C^{\prime} ; 0$ otherwise. A pair of data points, i and $j$, can fall into one of the following categories (S meaning Same and D meaning Different):

$$
\begin{aligned}
& S S: C_{i j}=1 \text { and } P_{i j}=1 \\
& D D: C_{i j}=0 \text { and } P_{i j}=0 \\
& S D: C_{i j}=1 \text { and } P_{i j}=0 \\
& D S: C_{i j}=0 \text { and } P_{i j}=1
\end{aligned}
$$

1. Rand index - With the above notation, the Rand index is defined as:

$$
\begin{equation*}
\text { Rand }=\frac{|S S|+|D D|}{|S S|+|S D|+|D S|+|D D|} \tag{2.1}
\end{equation*}
$$

2. Jaccard coefficient - A potential problem with Rand index is that the figure $|D D|$ can be very high, hence skewing the result. In order to get around this problem, the Jaccard coefficient is defined as:

$$
\begin{equation*}
\text { Jaccard }=\frac{|S S|}{|S S|+|S D|+|D S|} \tag{2.2}
\end{equation*}
$$

3. Corrected Rand index - Milligan (1986) has corrected the Rand index for chance, and the resulting index is called the Corrected Rand index. Corrected Rand (CR) is defined as:

$$
\begin{equation*}
C R=\frac{\sum_{i=1}^{m} \sum_{j=1}^{n}\binom{n_{i j}}{2}-\binom{n}{2}^{-1} \sum_{i=1}^{m}\binom{n_{i *}}{2} \sum_{j=1}^{n}\binom{n_{* j}}{2}}{\frac{1}{2}\left[\sum_{i=1}^{m}\binom{n_{i *}}{2}+\sum_{j=1}^{n}\binom{n_{* j}}{2}\right]-\binom{n}{2}^{-1} \sum_{i=1}^{m}\binom{n_{i *}}{2} \sum_{j=1}^{n}\binom{n_{* j}}{2}} \tag{2.3}
\end{equation*}
$$

where $n_{i j}$ represents the number of points in cluster $P_{i}$ and $C_{j}, n_{i *}$ indicates the number of points in cluster $P_{i}, n_{* j}$ indicates the number of points in cluster $C_{j}$, and $n$ is the total number of points.

## Internal indices

Ground truth may not always be available. In such cases, internal indices are computed to quantitatively assess clustering. Internal indices try to evaluate two aspects that any good clustering algorithm should possess: cohesion - how similar or how close are points belonging to the same cluster, and separation - how dissimilar or how far are points belonging to different clusters. Most common internal indices use Sum of Squared Error (or SSE) computation. Cohesiveness of a cluster is measured by sum of squares of intracluster distances between the points in a cluster. This quantity, called WSS, is given by:

$$
\begin{equation*}
W S S=\sum_{i} \sum_{x \in C_{i}}\left(x-m_{i}\right)^{2} \tag{2.4}
\end{equation*}
$$

where, $i$ is the index over the number of clusters, $x$ is a data point, $C_{i}$ is the $i^{\text {th }}$ cluster, and $m_{i}$ is the centroid of the $i^{\text {th }}$ cluster.

Separation is measured by sum of squares of inter-cluster distances. This quantity, called BSS, is the given by:

$$
\begin{equation*}
B S S=\sum_{i}\left|C_{i}\right|\left(m-m_{i}\right)^{2} \tag{2.5}
\end{equation*}
$$

where, $i$ is the index over the number of clusters, $\left|C_{i}\right|$ is the number of points assigned to the $i^{t h}$ cluster, $m$ is the centroid of the whole data set, and $m_{i}$ is the centroid of the $i^{\text {th }}$ cluster. It is clear that a good clustering algorithm would aim to increase BSS and reduce WSS. A property of these indices is that their sum (i.e. WSS+BSS) is a constant and larger number of tight clusters result in smaller WSS. In fact, the ratio BSS/WSS is used an indicator of the quality of clustering.

As seen, external indices are measured with respect to the ground truth, which is ideal in terms of a quantitative measurement of clustering performance, but not always is a labeling of the data available and one needs to resort to internal indices. Internal indices give a quantitative assessment of what are actually qualitative heuristics, such as compactness or exclusivity of clusters, and do not depend on an external labeling. Such indices are likely to be subject to interpretation, and the significance of these indices to our experiments will be discussed in later chapters.

## Relative Indices

Apart from the above kinds of indices, there is a third kind of index - the relative index. Relative indices are used primarily to compare various clustering algorithms or results. Relative indices can be used to find good values for input parameters of certain algorithms. Given below are three such relative indices.

1. Silhouette index: For a given cluster, $C_{j}(j=1, \ldots, m)$, this method assigns to each sample of $C_{j}$ a quality measure, $s(i)(i=1, \ldots, n)$, known as the Silhouette width. The Silhouette width is a confidence indicator on the membership of the $i^{\text {th }}$ sample in cluster $C_{j}$. The Silhouette width for the $i^{\text {th }}$ sample in cluster $C_{j}$ is defined as:

$$
\begin{equation*}
s(i)=\frac{b(i)-a(i)}{\max \{a(i), b(i)\}} \tag{2.6}
\end{equation*}
$$

where $a(i)$ is the average distance between the $i^{t h}$ sample and all of the samples included in $C_{j}$, and $b(i)$ is the minimum average distance between the $i^{t h}$ sample and all of the samples clustered in $C_{k}(k=1, \ldots, m ; k \neq j)$. From this formula it follows that $-1 \leq s(i) \leq 1$. When a $s(i)$ is close to 1 , one may infer that the $i^{t h}$ sample has been well clustered, i.e. it was assigned to an appropriate cluster. When a $s(i)$ is close to zero, it suggests that the $i^{t h}$ sample could also be assigned to the nearest neighboring cluster. If $s(i)$ is close to -1 , one may argue that such a sample has been misclassified. Thus, for a given cluster, $C_{j}(j=1, \ldots, m)$, it is possible to calculate a cluster Silhouette $S_{j}$, which characterizes the heterogeneity and isolation properties of such a cluster:

$$
\begin{equation*}
S_{j}=\frac{1}{n} \sum_{i=1}^{n} s(i) \tag{2.7}
\end{equation*}
$$

where n is number of samples in $C_{j}$. It has been shown that for any partition $U \leftrightarrow C$ : $C_{1}, C_{2}, \ldots C_{m}$, a Global Silhouette value, $G S_{u}$, can be used as an effective validity index.

$$
\begin{equation*}
G S_{u}=\frac{1}{m} \sum_{j=1}^{m} S_{j} \tag{2.8}
\end{equation*}
$$

Furthermore, it has been demonstrated that equation can be applied to estimate the most appropriate number of clusters for the data set. In this case the partition with the maximum $G S_{u}$ is taken as the optimal partition.
2. Dunn's Index: This index identifies sets of clusters that are compact and well separated. For any partition, U , produced by a clustering algorithm, let $C_{i}$ represent the $i^{\text {th }}$ cluster, the Dunn's validation index, D, is defined as:

$$
\begin{equation*}
D(U)=\min _{1 \leq i \leq m}\left\{\min _{\substack{1 \leq i \leq m \\ j \neq i}}\left\{\frac{\delta\left(C_{i}, C_{j}\right)}{\max _{1 \leq k \leq m}\left\{\Delta\left(C_{k}\right)\right\}}\right\}\right\} \tag{2.9}
\end{equation*}
$$

where $\delta\left(C_{i}, C_{j}\right)$ defines the distance between clusters $C_{i}$ and $C_{j}$ (intercluster distance); $\Delta\left(C_{k}\right)$ represents the intracluster distance of cluster $C_{k}$, and $m$ is the number of clusters of partition. The main goal of this measure is to maximize intercluster distances whilst minimizing
intracluster distances. Thus large values of D correspond to good clusters. Therefore, the number of clusters that maximizes D is taken as the optimal number of clusters, $m$.
3. Davies-Bouldin Index: Like the Dunns index, the Davies-Bouldin index aims at identifying sets of clusters that are compact and well separated. The Davies-Bouldin validation index, DB , is defined as:

$$
\begin{equation*}
D B(U)=\frac{1}{m} \sum_{i=1}^{m} \max _{j \neq i}\left\{\frac{\Delta\left(C_{i}\right)+\Delta\left(C_{j}\right)}{\delta\left(C_{i}, C_{j}\right)}\right\} \tag{2.10}
\end{equation*}
$$

where $U, \delta\left(C_{i}, C_{j}\right), \Delta\left(C_{i}\right), \Delta\left(C_{j}\right)$ and $m$ are defined as in equation (2.9). Small values of DB correspond to clusters that are compact, and whose centers are far away from each other. Therefore, the cluster configuration that minimizes DB is taken as the optimal number of clusters, $m$.

### 2.1.3 Approaches to clustering gene expression time-course data

Given the various clustering algorithms and validation techniques, there are a multitude of combinations one can use to cluster a data set and validate the cluster. Clustering algorithms and validation techniques use basic distance, intercluster and intracluster distance metrics in the evaluation of cost function. Below, we give commonly used distance metrics. The following notation has been used in the description of the metrics: $\boldsymbol{x}$ and $\boldsymbol{y}$ denote points in $n$-dimensional space, and the components of the points be $x_{1}, x_{2}, \ldots, x_{n}$. Let $S$ and $T$ denote two clusters.

## Basic distance metrics

The distance between two data points (genes) can be one of the following:

1. Euclidean distance: For any two points, the Euclidean distance between then is geometric distance between them in the $n$-dimensional space. Euclidean distance is the 2-norm (sometimes called the Euclidean norm), and is given by

$$
d=\left(\sum_{i=1}^{n}\left(x_{i}-y_{i}\right)^{2}\right)^{\frac{1}{2}}
$$

2. Manhattan distance: between two points in an Euclidean space is the sum of the lengths of the projections of the line segment between the points onto the coordinate axes. Manhattan distance is also called the 1-norm or taxicab distance, and is given by

$$
d=\sum_{i=1}^{n}\left(x_{i}-y_{i}\right)
$$

3. Correlation similarity: The correlation between two $n$-dimensional points can be used a similarity measure between the two genes. As an example, the Pearson correlation coefficient between two $n$-dimensional points is given by

$$
d=\frac{\sum_{i=1}^{n}\left(x_{i}-\mu_{x}\right)\left(y_{i}-\mu_{y}\right)}{(n-1) \sigma_{x} \sigma_{y}}
$$

where $\mu_{x}$ is the mean of $x$, and $\sigma_{x}$ is its standard deviation.
4. Cosine similarity: If the data points can be considered as vectors in an $n$-dimensional space, then the ratio of the dot product of the vectors to the product of their magnitudes gives the cosine of the angle between the vectors. This value can be used as a similarity measure between the vectors. The cosine distance between two points is given by

$$
d=\frac{\sum_{i=1}^{n} x_{i} y_{i}}{\sqrt{\left(\sum_{i=1}^{n} x_{i}^{2}\right)\left(\sum_{i=1}^{n} y_{i}^{2}\right)}}
$$

5. Probabilistic: A probabilistic model can be used to evaluate the distance between two data points. The probabilistic score obtained by such a model can be used as a similarity measure between the two points.

The last three measures are similarity measures, hence their inverse is used as a distance measure. These measures are, strictly speaking, not distance measures as they may not satisfy the triangle inequality property, however they still find heavy usage in clustering.

## Intercluster distance metrics

1. The single linkage distance defines the closest distance between two points belonging to two different clusters.
2. The complete linkage distance represents the distance between the most remote points belonging to two different clusters.
3. The average linkage distance defines the average distance between all of the points belonging to two different clusters.
4. The centroid linkage distance reflects the distance between the centers of two clusters.
5. The average of centroids linkage represents the distance between the center of a cluster and all of samples belonging to a different cluster.

## Intracluster distance metrics

1. The complete diameter distance represents the distance between the most remote points belonging to the same cluster.
2. The average diameter distance defines the average distance between all the points belonging to the same cluster.
3. The centroid diameter distance reflects the double average distance between all of the points and the centroid of the cluster.

### 2.1.4 Tree based metrics

Hierarchical clustering algorithms give rise to a tree structure, in which the data points can be viewed as leaves and clusters are 'built' by merging points close to each other and this process continuing with the resulting clusters. The resultant tree-like structure is called a 'dendrogram' and has a property that the level at which two points are merged is indicative of the proximity of the points. The process of merging continues all the way to the point we have one cluster. And a partition of the data can be obtained by 'severing' the dendrogram at a required level. Despite the
wide use of hierarchical clustering algorithms, there is very little literature on assessing the quality of dendrograms resulting from such algorithms. Wild et al. (2002) have devised three (related) quantitative measures which assess the quality of dendrogram, namely - Dendrogram purity, Leaf Harmony, and Leaf Disparity. Let $\mathcal{T}$ be a dendrogram tree structure and $\mathcal{C}$ be a set of class labels for the leaves of the tree.

1. Dendrogram $\operatorname{Purity}(\mathcal{T}, \mathcal{C})$ : Let $\mathcal{L}=\{1,2, \ldots, L\}$ be the set of leaves and $\mathcal{C}=\left\{c_{1}, c_{2}, \ldots, c_{L}\right\}$ be the class assignment for each leaf. Dendrogram purity is defined to be the measure obtained from the following random process: pick a leaf $l$ at random. Pick another leaf $j$ in the same class as $l$. Find the smallest subtree containing $l$ and $j$. Measure the fraction of leaves in that subtree which are in the same class as $l$ and $j$. The expected value of this fraction is the dendrogram purity. The overall tree purity is 1 if and only if all leaves in each class are contained within some pure subtree.
2. Leaf $\operatorname{Harmony}(l, \mathcal{T}, \mathcal{C})$ : Harmony is a measure of how well a leaf fits in. Given a leaf $l$, pick another leaf $j$ which belongs to the same class as $l$. Measure the fraction of leaves which belong to the same class as $l$ and $j$ in the smallest subtree that contain both these leaves. The expected value of this fraction is the Leaf Harmony for $l$. Harmony of each leaf is its contribution to the dendrogram purity.
3. Leaf Disparity highlights the differences between two hierarchical clusterings (i.e. dendrograms) of the same data. Intuitively, it measures for each leaf of one dendrogram how similar the surrounding subtree is to the corresponding subtree in other dendrogram.

Among the tree based metrics, we compute only the purity metric for our clustering results, while the rest find a mention here for completeness' sake.

In this chapter we have seen the different approaches to clustering data and the different metrics to evaluate a clustering partition. These methods and metrics are generally applicable to clustering in general. In the next chapter we see some of the specific approaches adopted by researchers over the years to cluster gene expression time-course data.

## Chapter 3

## Methods for clustering genes

Previous approaches to clustering time-course data fall broadly into two categories, depending on the way the time dimension was considered. The first class of methods disregard the temporal dependencies by considering the time points to be independent. Examples of this kind are kmeans, singular value decomposition techniques, and correlation analysis (to be described in detail). The second class is model-based approaches. Statistical models which account for time are used represent clusters. Distance function, generally, is not required as cluster membership is decided on maximizing the likelihood of data points. Methods which fall into this category are hidden Markov models, cubic splines, multivariate Gaussian etc.

### 3.1 Correlation analysis

One of the early methods to analyze gene expression data in time course was the use correlation as a distance measure between two genes. This method was adopted by Eisen et al. (1998). In correlation analysis, the distance between two genes is given by Pearson correlation coefficient. For two genes X and Y , both having $N$ time point observations, the similarity is given by:

$$
\begin{equation*}
S(X, Y)=\frac{1}{N} \sum_{i=1 . . N}\left(\frac{X_{i}-X_{o f f s e t}}{\Phi_{X}}\right)\left(\frac{Y_{i}-Y_{o f f s e t}}{\Phi_{Y}}\right) \tag{3.1}
\end{equation*}
$$

where

$$
\begin{equation*}
\Phi_{G}=\sqrt{\sum_{i=1 . . N} \frac{\left(G_{i}-G_{o f f s e t}\right)^{2}}{N}} \tag{3.2}
\end{equation*}
$$

When $G_{\text {offset }}$ is set to the mean of observation G , then $\Phi_{G}$ becomes the standard deviation of $G$, and $S(X, Y)$ the Pearson correlation coefficient. Inverse of correlation is used as a distance measure in a hierarchical agglomerative clustering procedure using average linkage criterion to merge the clusters bottom-up. Their work places emphasis not only on the clustering algorithms, but also on the visualization of clusters. To this end, a simple reordering of genes was used as a preprocessing step before building a dendrogram of the data points based on correlation coefficient. Dendrogram is a structure where relationships among objects (genes) are represented by a tree whose branch lengths reflect the degree of similarity between the objects. Figure 3.1 shows the visualization of clusters (after reordering) and the corresponding dendrogram as presented in Eisen et al. (1998).

While correlation analysis is able to identify major clusters in the data, the major drawback of this method is the disregarding of temporal dependencies. A complete understanding of the genetic regulatory network is not complete without understanding the causal relationships in regulation. Hence, it is of our opinion that correlation analysis is limited to identifying clusters of genes. Even for this solution, one needs to identify the point at which the dendrogram is to be severed to obtain cluster labels, which can be a difficult problem in an unsupervised setting such as theirs.

### 3.2 Statistical approaches to cluster time series data

Statistical approaches to cluster time series use statistical models like mixture models, hidden Markov models (HMM), autoregressive models and the like. The primary use of these models is to factor in the time dimension. We give a brief description of some of the statistical methods that have been used to solve this problem.

### 3.2.1 CAGED - Cluster analysis of gene expression dynamics

Ramoni et al. (2002) applied a Bayesian method for model-based clustering of gene expression time-course data (which they refer to as gene dynamics). Their method represents gene dynamics

Figure 3.1: Each point on the vertical axis corresponds to a single gene and time spans across the horizontal axis. Red indicates higher ratios while green indicates low ratios.
in the form of autoregressive equations, and use an agglomerative procedure to search the most probable partitioning of the data. The set of gene expression time-courses is supposed to have come about from an unknown number of stochastic processes. The task is then to iteratively merge time series into clusters, such that time series in a single cluster are generated by the same process. I briefly give an outline of the components that constitute CAGED.

1. Autoregressive models - Gene time-courses are cast in $p$ th order autoregressive framework, where $p$ specifies the the number of previous time steps that a single time step depends on. For example, if $p=2$, then the observation at time step $i, y_{i}$, depends on $y_{i-1}$ and $y_{i-2}$. The formulation also consists of an 'error' component, which is Gaussian distributed with mean 0 . This can be thought of as the noise component.
2. Probabilistic scoring metric - A set of $c$ clusters of time series is described as a statistical model, $M_{c}$, consisting of $c$ autoregressive models with coefficients and variance (of error). The posterior probability of the model is given by

$$
\begin{equation*}
P\left(M_{c} \mid y\right)=P\left(M_{c}\right) f\left(y \mid M_{c}\right) \tag{3.3}
\end{equation*}
$$

where $y$ is the data and $f\left(y \mid M_{c}\right)$ is the likelihood function. Assuming a uniform prior over the model, the posterior depends only on the likelihood factor, and this factor is used as the probabilistic scoring metric.
3. Agglomerative Bayesian Clustering - An agglomerative, finite-horizon search strategy that iteratively merges time series into clusters is then applied. The procedure starts by assuming that each of the $m$ observed time series is generated by a different process. The initial model, $M_{m}$, consists of $m$ clusters, one for each time series, with score $f\left(y \mid M_{m}\right)$. The next step is the computation of the marginal likelihood of the $m(m-1)$ models in which two of the $m$ series are merged into one cluster. The model $M_{m-1}$ with maximal marginal likelihood is chosen. If $f\left(y \mid M_{m}\right) \geq f\left(y \mid M_{m-1}\right)$ then no merging is accepted and the procedure stops. Else, two time series are merged into one cluster and the procedure repeats until no acceptable merging is found.
4. Heuristic search - The computational cost of the agglomerative clustering can be very high, in particular if the number of time-courses is large, then the merging procedure starts with that many initial clusters. In order to address this issue, the authors apply a heuristic search to find 'similar' clusters. Computing $m(m-1)$ similarity scores is more feasible than the earlier method of merging and computing likelihood. The intuition behind this being, similar clusters when merged are more likely to increase the marginal likelihood. The heuristics they apply to compute similarity is Euclidean distance (other metrics like correlation, Kullback-Leibler divergence can be applied as well). Once the merging of time series is done, the average profile of the cluster is computed by averaging over the two time series. Here again, the merging stops when no acceptable merging (that which increases the marginal likelihood) is found.

CAGED seems to be a simple and intuitive method to cluster gene expression time-courses. The authors have done an extensive comparison of the results obtained by CAGED to correlation analysis of Eisen et al. (1998). While the latter method identifies 8 clusters, CAGED identifies 4 clusters. CAGED, though simple, I believe, is not free from drawbacks. The heuristic search procedure does not completely alleviate the computational burden - once similar clusters have been found, the marginal likelihood still has to be calculated to see verify if merging will increase likelihood. It is not entirely clear how the 'average profile' is computed. A simple average of the constituting time series may not be the most principled way of averaging time series. Lastly, the number of time steps in each time-course could pose a problem. Autoregression may not perform as well as some other time-series models for long time series.

### 3.2.2 Finite HMM with Gaussian output

Since the data is a time series data, use of a traditional time series modeling technique like HMM makes sense. One of the most recent approaches to apply HMM to gene data in time-course was by Schliep et al. (2005). The authors have used mixtures of HMM and model collection techniques for the task. A brief description of their method is given below.

Their method consists of four major building blocks: First, hidden Markov models - to capture qualitative behavior of time-courses. Second, initial model collection (can be arrived at by various methods). Third, estimation of a finite mixture model using prior information in a par-
tially supervised clustering setting. Fourth, inferring groups from the mixture using entropy and thresholding.

Hidden Markov models have been used with great success for time series applications such as Part-of-Speech taggers, speech recognition, stock market analysis etc. Refer to Juang and Rabiner (1991) for a good overview of HMM and one of its applications. The principle behind HMM is that the observed sequence (in time) is a caused by a hidden sequence. The hidden sequence is a first order Markov chain (higher orders are possible as well) - where the hidden state at time $i, v_{i}$, depends only on the hidden state at time $i-1, v_{i-1}$. The number of hidden states is fixed before the model is learnt, and is usually done by trial-and-error or a model selection technique like Akaike Information criterion (AIC) or Bayesian Information criterion (BIC).

The algorithm used by Schliep et al. (2005) starts off with an initial collection of $k$ HMMs. This collection is obtained in one of the three ways: First, expert selection - in which an expert hand-crafts the models. Alternatively, one can start with an exhaustive collection of models encoding all prototypical methods. Second, randomized model collection. The authors suggest creating $k$ different $N$ state HMM with identical Gaussian emissions centered around zero. After which Baum-Welch training is performed until convergence with each of the $k$ models. Then the gene expression time-courses are weighted with random, uniform in $[0,1]$ weights per model. The resulting randomized model collection would explain random sub-populations of the data. Third, a Bayesian model collection technique based on Bayesian model merging by Stolcke and Omohundro (1993) is suggested as a technique to learn the initial collection. Here the states of $k N$-state HMM are first merged within HMM by identifying successive states whose merging decreases the likelihood the least. This kind of horizontal merging continues until an expert/user given input $N_{0}$ states per HMM is reached. After which, merging of states across the $k$ HMM takes place, again the criterion for merging being minimal loss of likelihood.

This step is then followed by formulating the whole problem as a mixture of HMMs, whose nonstatistical analogue is fuzzy clustering. Here, all the $k$ HMMs share responsibility for every time-course and the sum of responsibilities sum to 1 . Thus $k$ linear HMMs are combined to one probability density function. This mixture model can be optimized with the Expectation Maximization (Dempster et al. (1977)) algorithm to compute the maximum likelihood estimates.

The authors also suggest a partially supervised learning extension to the standard EM algorithm.
For inference and assignment of gene time-courses to clusters, entropy criterion is used. Each gene time-course is assigned to the cluster of maximal posterior, however to be more accurate with assignments, this step is preceded by a computation of the entropy over the mixture probabilities. If the entropy is below a certain user defined threshold, then such an assignment is carried out, else the gene is assigned to a different 'anonymous' cluster. The computation of entropy can be seen as the evaluation of ambiguity in cluster assignment.

This algorithm has been applied to two real gene expression time course data sets and two simulated data sets. Though the results look good, there are a number of places where expert input/intervention is required in this procedure. Below, we note some of the shortcomings of their method.

1. The number of HMMs $k$ in the mixture need to be fixed. The authors have suggested a BIC method to estimate the number of components in the mixture, but BIC is not without its problems. It can over or underestimate the number of true components.
2. In the Bayesian model collection technique, the number of states at which merging should stop is defined by the user/expert. Again, not something desirable.
3. The entropy threshold used in the inference step is also user input. Fixing entropy threshold (even aided by a visual interface as mentioned in the paper) is not the best way of fixing thresholds and at best captures the intuition of the user.

### 3.2.3 Other approaches

Among the other popular approaches that have been tried to model gene expression time-course data are piecewise polynomial curve fitting. We briefly discuss the idea given by Bar-Joseph et al. (2003). In the algorithm proposed by the authors, each expression profile is modeled as a cubic spline (piecewise polynomial) that is estimated from the observed data and every time point influences the overall smooth expression curve. They constrain the spline coefficients of genes in the same class to have similar expression patterns, while also allowing gene specific parameters. Their algorithm attempts to address three different problems which appear commonly in gene expression analysis

- missing value estimation, clustering and alignment. Missing value estimation can be performed only after the spline coefficients are known, hence the first task is to get an estimate of the spline coefficients. The authors present an algorithm called 'TimeFit' to estimate the spline coefficients and obtain clusters simultaneously. In brief, the algorithm takes the number of clusters, $c$, as an input and performs a modified EM (Dempster et al. (1977)). It starts of by assigning each class a gene at random, and estimating the spline coefficients (with suitable allowance for noise). This constitutes the E step. The M step maximizes the parameters for each class with respect to the class probability (as computed in the E step). We notice that this algorithm closely resembles the $k$-means algorithm we have seen earlier. They share the same drawbacks as well. Mainly, the number of clusters, $c$, needs to be given as an input, and secondly EM converges to a local minima, which means that initialization plays an important role in the clustering result.

In this chapter we have seen the different approaches researchers have taken towards clustering gene expression time-course data. In the next chapter we see the approach we propose. Since it's a novel method and is an application of the Hierarchical Dirichlet Process, introduced by Teh et al. (2004), a good part of the chapter is devoted to the explanation of Dirichlet Processes (DP) (Ferguson (1973)) and Hierarchical Dirichlet Processes (HDP). Parts of this chapter have been taken from Teh et al. (2004), Teh et al. (2006), and my colleague, Rahul Krishna's notes on DP, HDP, and their applications.

## Chapter 4

## The infinite hidden Markov model

Consider a situation which involves separation of data into groups, such that each data point is a draw from a mixture model but we also have the requirement that mixture components be shared across groups. This requirement is different from an ordinary mixture model (like a Gaussian mixture model) where each component has a 'responsibility' factor in producing each data point. Here, each group of data has its own mixture model and some of the components are common to two or more groups. Such a scenario lends itself naturally to hierarchical modeling - parameters are shared among different groups, and the randomness of the parameters induces dependencies among the groups. For example: Consider a problem from the field of Information Retrieval (IR). In document modeling, the occurrence of words in a document are considered to be conditionally independent of each other (Salton and McGill (1983)), conditioned on a 'topic' (analogous to a cluster). And each topic is modeled as a distribution over words from a vocabulary (Blei et al. (2003)). As an example, consider a document which talks of university funding. The words in this document might be drawn from topics like 'education' and 'finance'. If this document were a part of a corpus which also has other documents, say, one of which talks of university football, then the topics for this document may be 'education' and 'sports'. Thus we see that topics (or clusters) are shared across different groups of data (documents). The topic 'education' is shared among many different documents, and each document has its words drawn from several topics (one of which could be 'education'). As we shall see, the Hierarchical Dirichlet Process aims to solve such clustering problems.

Hierarchical Dirichlet Processes (HDP) was introduced by Teh et al. (2004), and is a nonparametric approach to model-based clustering. The data is divided into a set of $J$ groups, and the task is to find clusters within each group which capture the latent structure of the data in the group. The number of clusters within each group is unknown and is to be inferred from the data. Moreover, the clusters need to be shared across groups.

As a build-up to the HDP and Hierarchical Dirichlet Processes - Hidden Markov Model (HDPHMM), which is our approach to clustering gene expression time-course data, we'll see Dirichlet Processes (DP) and some of its characterizations which will help us better understand HDP and HDP-HMM.

### 4.1 Notation

Before we go into the detail of DP and HDP, lets make explicit the notation we will be following in this chapter. The data points or observations are organized into groups and observations are assumed to be exchangeable within groups. In particular, let $j \in\{1,2, \ldots J\}$ be the index for $J$ groups of data. Let $\boldsymbol{x}_{j}=\left(x_{j i}\right)_{i=1}^{n_{j}}$ denote the $n_{j}$ observations in group $j$. We assume that each observation $x_{j i}$ is conditionally independent draw from a mixture model, where the parameters of the mixture model are drawn once per group. We also assume that $\boldsymbol{x}_{1}, \boldsymbol{x}_{2}, \ldots \boldsymbol{x}_{J}$ are exchangeable at the group level. Let $\boldsymbol{x}=\left(\boldsymbol{x}_{j}\right)_{j=1}^{J}$ denote the entire data set.

If each observation is drawn independently from a mixture model, then there is a mixture component associated with each observation. Let $\theta_{j i}$ denote a parameter specifying the mixture component associated with observation $x_{j i}$. These $\theta_{j i}$ are also referred to as factors, and in general factors need not be distinct. Let $F\left(\theta_{j i}\right)$ denote the distribution of $x_{j i}$ given the factor $\theta_{j i}$. Let $G_{j}$ denote the prior distribution for the factors $\boldsymbol{\theta}_{j}=\left(\theta_{j i}\right)_{i=1}^{n_{j}}$ associated with the group $j$. Thus we have the following model:

$$
\begin{array}{ll}
\theta_{j i} \mid G_{j} \sim G_{j} & \text { for each } \mathrm{j} \text { and } \mathrm{i} \\
x_{j i} \mid \boldsymbol{\theta}_{j} \sim F\left(\theta_{j i}\right) & \text { for each } \mathrm{j} \text { and } \mathrm{i} \tag{4.2}
\end{array}
$$

In the next section, when we talk about Dirichlet Processes, we deal only with one group of data, hence the subscript denoting group will be dropped as needed.

### 4.2 Dirichlet Processes

The Dirichlet Process, $D P\left(\alpha, G_{0}\right)$, is a measure on measures. It has two parameters, a scaling parameter $\alpha>0$ and a base measure $G_{0}$. Ferguson (1973) defined DP as follows:

Definition 1: Let $\Theta$ be a continuous random variable, $G_{0}$ be a non-atomic probability distribution on $\Theta$, and $\alpha$ be a positive scalar. Let $G$ be a random variable denoting a probability distribution on $\Theta$. We say that $G$ is distributed by a Dirichlet Process with parameters $\alpha$ and $G_{0}$ if for all natural numbers, k , and k-partitions, $B$, on $\Theta$,

$$
\begin{equation*}
\left(G\left(\Theta \in B_{1}\right), G\left(\Theta \in B_{2}\right), \ldots, G\left(\Theta \in B_{k}\right)\right) \sim \operatorname{Dir}\left(\alpha G_{0}\left(B_{1}\right), \alpha G_{0}\left(B_{2}\right), \ldots, \alpha G_{0}\left(B_{k}\right)\right) \tag{4.3}
\end{equation*}
$$

Here, $G\left(\Theta \in B_{i}\right)$ is the probability of $\Theta \in B_{i}$ under the probability distribution $G$. Thus,

$$
G\left(\Theta \in B_{i}\right)=P\left(\Theta \in B_{i} \mid G\right)
$$

It can be noted that the Dirichlet distribution is a special case of the Dirichlet Process where $\Theta$ is finite and discrete.

We write $G \sim D P\left(\alpha, G_{0}\right)$ if $G$ is a random probability measure with distribution given by the Dirichlet Process.

Readers interested in foundations (definitions, theorems and proofs) of Dirichlet process may refer to Appendix A.

### 4.2.1 The Polya urn scheme and the Chinese restaurant process

The marginal probability of $\Theta \in B_{i}$ under the posterior is given by (A.8). The Polya urn model (Blackwell and MacQueen (1973)) gives another perspective of the Dirichlet process. It refers to draws from G. Consider a sequence of independently and identically distributed (i.i.d.) samples $\theta_{1}, \theta_{2}, \ldots, \theta_{n}$, distributed according to G. Blackwell and MacQueen (1973) showed that the proba-
bility distribution of the $(n+1)^{t h}$ sample given the previous $n$ samples, after integrating out $G$, is given by:

$$
P\left(\theta_{n+1} \mid \theta_{1}, \ldots, \theta_{n}\right)=\frac{\alpha}{\alpha+n} G_{0}+\frac{1}{\alpha+n} \sum_{i=1}^{n} \delta_{\theta_{i}}
$$

where $\delta_{\theta}$ is a point mass at $\theta$.
This conditional distribution can be interpreted in terms of the Polya urn model (Blackwell and MacQueen (1973)) in which a ball of a distinct color is associated with each atom $\theta_{i}$. The balls are contained in urns such that each urn contains balls of a single color and all balls of a single color are in the same urn. When a ball is drawn from an urn, the ball is placed back in the urn with an additional ball of the same color. The probabilities of choosing new urns and of choosing a previously chosen urn are given by (4.7) and (4.6) respectively. See Appendix A for further details (A. 11 and A.10). The probability of seeing a given sequence of colors $\boldsymbol{\theta}$ is given by

$$
\begin{align*}
P\left(\theta_{1}, \ldots, \theta_{n}\right) & =P\left(\theta_{1}\right) P\left(\theta_{2} \mid \theta_{1}\right) \ldots P\left(\theta_{n} \mid \theta_{1}, \ldots, \theta_{n-1}\right)  \tag{4.4}\\
& =\prod_{i=1}^{n} \frac{\alpha G_{0}\left(\theta_{i}\right)+\sum_{j=1}^{i-1} \delta_{\theta_{j}}\left(\theta_{i}\right)}{\alpha+i-1} \tag{4.5}
\end{align*}
$$

Another interpretation of the conditional distribution of (A.8) is in terms of the Chinese restaurant process (Aldous (1985)), which is closely related to the Polya urn model. In this analogy, a restaurant has a countably infinite collection of empty tables. The first customer who arrives sits at an empty table. Subsequent customers can either sit at an empty table, or sit at an already occupied table. The probabilities of a new customer sitting at an occupied or an empty table are given by 4.6 and 4.7, respectively. See Appendix A for further details (A. 10 and A.11). Interpretation of these equations in terms of the Chinese restaurant process is deferred until the 'clustering effect' of Dirichlet process is explained.

$$
\begin{align*}
& P\left(\theta_{n+1}=\theta_{i} \text { for } 1 \leq i \leq n \mid \theta_{1}, \ldots, \theta_{n}, \alpha, G_{0}\right)=\frac{1}{\alpha+n} \sum_{j=1}^{n} \delta_{\theta_{j}}\left(\theta_{n+1}\right)  \tag{4.6}\\
& P\left(\theta_{n+1} \neq \theta_{i} \text { for } 1 \leq i \leq n \mid \theta_{1}, \ldots, \theta_{n}, \alpha, G_{0}\right)=\frac{\alpha}{\alpha+n} \tag{4.7}
\end{align*}
$$

Figure 4.1: A depiction of the Chinese restaurant after eight customers have been seated. Customers ( $\theta_{i}$ 's) are seated at tables (circles) which correspond to unique values $\phi_{k}$.

Above equations show the 'clustering effect' of DPs. This clustering property exhibited from the conditional distributions can be made more explicit by introducing a new set of variables that represent the distinct values of the atoms. We define $\phi_{1}, \ldots, \phi_{K}$ to be the distinct values taken by $\theta_{1}, \ldots, \theta_{n}$, and $m_{k}$ to be the number of values of $\theta_{i^{\prime}}$ that are equal to $\phi_{k}, 1 \leq i^{\prime} \leq n$. We can re-write (A.8) as

$$
\begin{equation*}
P\left(\theta_{n+1} \mid \theta_{1}, \ldots, \theta_{n}\right)=\frac{\alpha}{\alpha+n} G_{0}+\sum_{k=1}^{K} \frac{m_{k}}{\alpha+n} \delta_{\phi_{k}} \tag{4.8}
\end{equation*}
$$

Thus, with respect to the Chinese restaurant process analogy, the customers are $\theta_{i}$ 's and the tables are $\phi_{k}$ 's. Figure 4.1 depicts the Chinese restaurant process. We can observe from (4.8) above, that the probability of a new customer occupying an empty table is proportional to $\alpha$ and the probability of a new customer occupying an occupied table is proportional to the number of customers already at that table. By drawing from a Dirichlet process, a partitioning of $\Theta$ is induced, and the Chinese restaurant process and the Polya urn model define the corresponding distribution over these partitions.

We can observe from (4.4) and (4.5) above that the ordering of $\theta$ 's does not matter. Thus the Polya Urn model and the Chinese restaurant process yield exchangeable distributions on partitions.

From the definition of exchangeability (see Appendix A), it is reasonable to act as if there is an underlying parameter and a prior on that parameter, and that the data are conditionally i.i.d. given that parameter. This justifies the graphical model for a Dirichlet process is given in Figure 4.2. Here, $G$, the draw from a Dirichlet process, can be considered such a parameter.

Figure 4.2: Graphical model representing the Dirichlet process. The rectangular plate has the effect of repeating the $\theta_{i}$ node from $i=1, \ldots, n$.

### 4.2.2 The stick-breaking construction

The stick-breaking construction (Sethuraman (1994)) gives an explicit representation of the draw from a Dirichlet Process. If $G \sim D P\left(\alpha, G_{0}\right)$ and samples from $G$ can be represented as

$$
\begin{equation*}
G=\sum_{k=1}^{\infty} \pi_{k} \delta_{\phi_{k}} \tag{4.9}
\end{equation*}
$$

where $\phi_{k} \sim G_{0}, \sum_{k=1}^{\infty} \pi_{k}=1$, and $\delta_{\phi}$ is a probability measure concentrated at $\phi$.

$$
\begin{equation*}
\pi_{k}=\pi_{k}^{\prime} \prod_{j=1}^{k-1}\left(1-\pi_{j}^{\prime}\right) \tag{4.10}
\end{equation*}
$$

and

$$
\begin{equation*}
\pi_{k}^{\prime} \sim \operatorname{Beta}(1, \alpha) \tag{4.11}
\end{equation*}
$$

That is, $G \sim D P\left(\alpha, G_{0}\right)$ can be written as an infinite sum of spikes. Thus, a draw from a Dirichlet Process is discrete with probability 1. If we consider a stick of unit length, the $\pi_{k}$ 's can be represented as the length of the stick that is broken off from the remaining length after $k-1$ pieces have been broken off. We may interpret $\boldsymbol{\pi}$ as a random probability measure on the positive integers.

Figure 4.3: Graphical model representing the Dirichlet process mixture model

### 4.2.3 Dirichlet process mixture model

An important application of the Dirichlet Process is the Dirichlet Process mixture model. Here, a Dirichlet Process is used as a non-parametric prior on the parameters of a mixture model. Let $x_{i}$ be the observations that arise as follows:

$$
\begin{align*}
\theta_{i} \mid G & \sim G  \tag{4.12}\\
x_{i} \mid \theta_{i} & \sim F\left(\theta_{i}\right) \tag{4.13}
\end{align*}
$$

where $F\left(\theta_{i}\right)$ denotes the distribution of the observations given $\theta_{i}$. When $G$ is distributed according to a Dirichlet Process, this models is referred to as a Dirichlet Process mixture model. A graphical model representation of the Dirichlet Process mixture model is given in Figure 4.3.

In terms of the Chinese Restaurant Process, the customers are the $\theta_{i}$ 's and sit at tables that represent the parameters of the distribution $F\left(\theta_{i}\right)$. For example, in the case that $F($.$) is a Normal$ distribution, $\theta_{i}$ would be the $(\mu, \sigma)$ pairs. The prior distribution over $\theta_{i}$ is given by $G$. A new customer either samples a new $\theta$ (i.e. an unoccupied table) or joins in with an already sampled $\theta$. The distribution over which table $\theta_{i}$ joins, given the previous samples, is given by the conditional distributions governing the Chinese restaurant process.

In terms of the stick-breaking construction, the $\theta_{i}$ 's take on values $\phi_{k}$ with probability $\pi_{k}$. We can indicate this using an indicator variable $z_{i}$, which specifies the 'cluster number' of each observed datapoint $x_{i}$. Hence we have the stick-breaking representation of the Dirichlet Process mixture model as:

$$
\begin{aligned}
\pi_{k} \mid \alpha & \sim \beta_{k} \prod_{j=1}^{k-1}\left(1-\beta_{j}\right) \\
z_{i} \mid \boldsymbol{\pi} & \sim \boldsymbol{\pi} \\
\phi_{k} \mid G_{0} & \sim G_{0} \\
x_{i} \mid z_{i},\left(\phi_{k}\right)_{k=1}^{\infty} & \sim F\left(\phi_{z_{i}}\right)
\end{aligned}
$$

where $G=\sum_{k=1}^{\infty} \pi_{k} \delta_{\phi_{k}}$ and $\theta_{i}=\phi_{z_{i}}$.

### 4.3 Hierarchical Dirichlet processes

The Hierarchical Dirichlet Process (Teh et al. (2006)) has been used for the modeling of grouped data, where each group is associated with a mixture model, and where it is desired to link these mixture models by sharing mixture components between groups. A Hierarchical Dirichlet Process is a distribution over a set of random probability measures over $\Theta$. The process defines a set of random probability measures $\left(G_{j}\right)_{j=1}^{J}$, one for each group, and a global random probability measure $G_{0}$. The global measure $G_{0}$ is distributed as a Dirichlet Process with concentration parameter $\gamma$ and base probability measure $H$ :

$$
G_{0} \mid \gamma, H \sim D P(\gamma, H)
$$

The random probability measures $G_{j}$ are conditionally independent given $G_{0}$, and are distributed as:

$$
G_{j} \mid \alpha, G_{0} \sim D P\left(\alpha, G_{0}\right)
$$

Each of the priors $G_{j}$ are used as priors on the parameters of the mixture model for the $j^{\text {th }}$ group. That is:

$$
\begin{aligned}
\theta_{j i} \mid G_{j} & \sim G_{j} \\
x_{j i} \mid \theta_{j i} & \sim F\left(\theta_{j i}\right)
\end{aligned}
$$

## The graphical model is shown in 4.4

It is important to note that $G_{0}$ is a draw from a Dirichlet Process. Supposing instead that each of the $G_{j}$ 's are drawn from a single underlying Dirichlet Process $D P\left(\alpha, G_{0}(\tau)\right)$, where $G_{0}(\tau)$ is a parametric distribution with random parameter $\tau$, there would be no sharing possible. This is due to the fact that even though the samples from each of the $G_{j}$ 's are discrete, they would have no atoms in common as the common base measure $G_{0}(\tau)$ is continuous. That is $P\left(\theta_{j_{1} a}=\phi_{k}, \theta_{j_{2} b}=\phi_{k}\right)=0$. This can be avoided by using a discrete distribution $G_{0}$ as the base measure, but this would no longer yield flexible models. By making $G_{0}$ a draw from a Dirichlet process, $G_{0} \sim D P(\gamma, H)$ is discrete and yet has broad support, and necessarily, each of the $G_{j}$ 's has support at the same points and hence sharing is possible.

### 4.3.1 The stick-breaking construction

The global measure $G_{0}$ for the groups is distributed as a Dirichlet Process, and using the stick breaking representation, we can write:

$$
G_{0}=\sum_{k=1}^{\infty} \beta_{k} \delta_{\phi_{k}}
$$

Since $G_{0}$ has support at the points $\phi=\left(\phi_{k}\right)_{k=1}^{\infty}$, each $G_{j}$ necessarily has support over these points as well and thus:

$$
G_{j}=\sum_{k=1}^{\infty} \pi_{j k} \delta_{\phi_{k}},
$$

Figure 4.4: Graphical model representing the hierarchical Dirichlet process

We know from (4.10) and (4.11) that the variable $\beta_{k}$ is defined by:

$$
\begin{aligned}
\beta_{k} & =\beta_{k}^{\prime} \prod_{l=1}^{k-1}\left(1-\beta_{l}^{\prime}\right) \\
\beta_{k}^{\prime} & \sim \operatorname{Beta}(1, \gamma)
\end{aligned}
$$

It can be shown (Teh et al. (2006)) that $\boldsymbol{\pi}_{\boldsymbol{j}} \sim D P(\alpha, \boldsymbol{\beta})$ and that the relation between the groups weight $\pi_{j k}$ and the global weights $\beta_{k}$ is given by

$$
\begin{align*}
& \pi_{j k}=\pi_{j k}^{\prime} \prod_{l=1}^{k-1}\left(1-\pi_{j l}^{\prime}\right)  \tag{4.14}\\
& \pi_{j k}^{\prime} \sim \operatorname{Beta}\left(\alpha \beta_{k}, \alpha\left(1-\sum_{l=1}^{k} \beta_{l}\right)\right) \tag{4.15}
\end{align*}
$$

### 4.3.2 The Chinese restaurant franchise

The Chinese restaurant franchise is an analogue of the Chinese restaurant process for hierarchical Dirichlet processes. The metaphor is that there is a restaurant franchise with a shared menu across

Figure 4.5: Graphical model representing the stick breaking construction for hierarchical Dirichlet process
restaurants. At each table, of each restaurant one dish is ordered from the menu by the first customer who sits there and will be shared by all customers who join at that table. Thus, multiple tables in multiple restaurants can serve the same dish.

The restaurants correspond to the groups and the customers correspond to $\theta_{j i}$. The global menu of dishes is represented by $\phi_{1}, \ldots, \phi_{k}$ which are distributed according to $H$. The following set of variables are defined:
$\psi_{j t}$ : Dish served at table $t$ in restaurant $j$.
$t_{j i}$ : Index of $\psi_{j t}$ associated with $\theta_{j i}$
$k_{j t}$ : Index of $\phi_{k}$ associated with $\psi_{j t}$
Thus, customer $i$ sits at table $t_{j i}$ in restaurant $j$, and table $t$ in restaurant $j$ served dish $k_{j t}$.
$n_{j t k}$ : Number of customers in restaurant $j$ at table $t$ eating dish $k$.
$m_{j k}$ : Number of tables in restaurant $j$ serving dish $k$.
Marginal counts will be represented by dots. Thus:
$n_{j t .}$ : number of customers at table $t$
$n_{j . k}$ : number of customers eating dish $k$ at restaurant $j$.
$m_{j \text {. }}$ : number of tables in the restaurant $j$
$m_{. k}$ : number of tables serving dish $k$
$m_{\text {..: total number of tables occupied }}$

We can write the conditional probabilities of $\theta_{j i}$ given the previous $i-1$ samples at restaurant $j$ and 0 by integrating out $G_{j}$. From (4.8),

$$
\begin{equation*}
\theta_{j i} \mid \theta_{j 1}, \ldots, \theta_{j, i-1}, \alpha, G_{0} \sim \sum_{t=1}^{m_{j}} \frac{n_{j t .}}{\alpha+i-1} \delta_{\psi_{j t}}+\frac{\alpha}{\alpha+i-1} G_{0} \tag{4.16}
\end{equation*}
$$

Next, by integrating out $G_{0}$, we can compute the conditional distribution of $\psi_{j t}$ as:

$$
\begin{equation*}
\psi_{j t} \mid \psi_{11}, \psi_{12}, \ldots, \psi_{21}, \ldots, \psi_{j, t-1}, \gamma, H \sim \sum_{k=1}^{K} \frac{m_{. k}}{m_{. .}+\gamma} \delta_{\phi_{k}}+\frac{\gamma}{m_{. .}+\gamma} H \tag{4.17}
\end{equation*}
$$

where $K$ is the total number of dishes.

### 4.4 The infinite hidden Markov model

### 4.4.1 Hidden Markov models

Hidden Markov models (HMM) are a popular statistical model used to model time series data. They have found wide usage in speech recognition, natural language processing, information retrieval, and other time series data applications like stock market prediction. Early HMM theory was developed by Baum and Petrie (1966) and Baum et al. (1970). A HMM models a sequence of observations $\boldsymbol{y}_{1: T}=\left\{y_{1}, \ldots, y_{T}\right\}$ by assuming that the observation at time $t, y_{t}$, was produced by a hidden state $v_{t}$, and the sequence of hidden states $\boldsymbol{v}_{1: T}=\left\{v_{1}, \ldots, v_{T}\right\}$ was generated by a first-order Markov process. The complete data likelihood of the sequence, of length $T$, is given by:

$$
\begin{equation*}
p\left(\boldsymbol{v}_{1: T}, \boldsymbol{y}_{1: T}\right)=p\left(v_{1}\right) p\left(y_{1} \mid v_{1}\right) \prod_{t=2}^{T} p\left(v_{t} \mid v_{t-1}\right) p\left(y_{t} \mid v_{t}\right) \tag{4.18}
\end{equation*}
$$

where $p\left(v_{1}\right)$ is the initial probability of first hidden state, $p\left(v_{t} \mid v_{t-1}\right)$ is the transition probability going from $v_{t-1}$ to $v_{t}$, and $p\left(y_{t} \mid v_{t}\right)$ is the probability of 'emitting' the observable $y_{t}$ while in hidden state $v_{t}$. For a simple HMM, it is assumed that there are a fixed number of hidden states (say ' $k$ ') and a fixed number of observable symbols (say ' p ') and that the transition probabilities are stationary. With these assumptions, the parameter, $\boldsymbol{\theta}$, of the model comprises of the state transition
probabilities, $\boldsymbol{A}$, the emission probabilities, $\boldsymbol{C}$, and the initial state prior, $\boldsymbol{\pi}$. That is:

$$
\begin{equation*}
\boldsymbol{\theta}=(\boldsymbol{A}, \boldsymbol{C}, \boldsymbol{\pi}) \tag{4.19}
\end{equation*}
$$

where

$$
\begin{array}{rlrl}
\boldsymbol{A} & =\left\{a_{j j^{\prime}}\right\}: a_{j j^{\prime}}=p\left(v_{t}=j^{\prime} \mid v_{t-1}=j\right) & & k \times k \text { state transition matrix } \\
\boldsymbol{C} & =\left\{c_{j m}\right\}: c_{j m}=p\left(y_{t}=m \mid v_{t}=j\right) & & k \times p \text { emission matrix } \\
\boldsymbol{\pi} & =\left\{\pi_{j}\right\}: \pi_{j}=p\left(v_{1}=j\right) & k \times 1 \text { initial state vector } \tag{4.22}
\end{array}
$$

obeying the normalization constraints:

$$
\begin{align*}
\boldsymbol{A} & =\left\{a_{j j^{\prime}}\right\}: \sum_{j^{\prime}=1}^{k} a_{j j^{\prime}}=1 \quad \forall j  \tag{4.23}\\
\boldsymbol{C} & =\left\{c_{j m}\right\}: \sum_{m=1}^{p} c_{j m}=1 \quad \forall j  \tag{4.24}\\
\boldsymbol{\pi} & =\left\{\pi_{j}\right\}: \sum_{j=1}^{k} \pi_{j}=1 \tag{4.25}
\end{align*}
$$

Parameter estimation in an HMM is done using the Baum-Welch algorithm (Baum et al. (1970)), which is an EM algorithm used to find the ML estimate of the parameters. Briefly, the M step consists of finding those settings of $\boldsymbol{A}, \boldsymbol{C}$ and $\boldsymbol{\pi}$ which maximize the probability of the observed data, and the E step (known as forward-backward algorithm for HMMs) amounts to calculating the expected count of the particular transition-emission pair, employing a dynamic programming trick. For more details on the Baum-Welch algorithm, refer to Baum et al. (1970).

### 4.4.2 HDP-HMM

To understand the hidden Markov model in the HDP framework, it is easier to view hidden Markov model of the previous subsection in a different way than presented there, and then relate it to the stick-breaking construction of section 4.3.1. The work here can be found in the HDP paper, which interestingly was originally inspired by an infinite hidden Markov model paper by Beal et al. (2002).

A hidden Markov model is a doubly stochastic Markov chain in which a sequence of multinomial 'state' variables $\left\{v_{1}, \ldots, v_{T}\right\}$ are linked via a state transition matrix, and each element $y_{t}$ in a sequence of 'observations' $\left\{y_{1}, \ldots, y_{T}\right\}$ is drawn independently of the other observations conditional on $v_{t}$ (Rabiner (1989)). HMM is a dynamic variant of a finite mixture model, in which there is one mixture component corresponding to each value of the multinomial state. Note that the HMM involves not a single mixture model, but rather a set of mixture models: one for each value of the current state. That is, the 'current state' $v_{t}$ indexes a specific row of the transition matrix, with the probabilities in this row serving as the mixing proportions for the choice of the 'next state' $v_{t+1}$. Given the next state $v_{t+1}$, the observation $y_{t+1}$ is drawn from the mixture component indexed by $v_{t+1}$.

The stick breaking representation makes explicit the generation of one set of (countably infinite) set of parameters $\left(\phi_{k}\right)_{k=1}^{\infty}$; the $j$ th group has access to various of these parameters to model its data $\left(x_{j i}\right)_{i=1}^{n_{j}}$, depending on the sampled mixing proportion $\boldsymbol{\pi}_{j}$.

Thus, to consider a nonparametric variant of the HMM which allows an unbounded set of states, we must consider a set of DPs, one for each value of the current state. Moreover, these DPs must be linked, because we want the same set of 'next states' to be reachable from each of the 'current states'. This amounts to the requirement that the atoms associated with the state-conditional DPs should be shared - exactly the framework of the hierarchical DP. Thus, we simply replace the set of conditional finite mixture models underlying the classical HMM with an HDP, and the resulting model, an HDP-HMM, provides an alternative to methods that place an explicit parametric prior on the number of states or make use of model selection methods to select a fixed number of states (e.g. Stolcke and Omohundro (1993)).

Consider the unraveled hierarchical Dirichlet process representation shown in Figure 4.6. The

Figure 4.6: Graphical model representing the stick breaking construction for HDP-HMM
parameters in this representation have the following distributions:

$$
\begin{align*}
\boldsymbol{\beta} \mid \gamma & \sim \operatorname{Stick}(\gamma)  \tag{4.26}\\
\boldsymbol{\pi}_{k} \mid \alpha_{0}, \boldsymbol{\beta} & \sim \operatorname{DP}\left(\alpha_{0}, \boldsymbol{\beta}\right) \\
v_{t} \mid v_{t-1},\left(\boldsymbol{\pi}_{k}\right)_{k=1}^{\infty} & \sim \boldsymbol{\pi}_{v_{t-1}} \\
\phi_{k} \mid H & \sim H \\
y_{t} \mid v_{t},\left(\phi_{k}\right)_{k=1}^{\infty} & \sim F\left(\phi_{v_{t}}\right)
\end{align*}
$$

where we assume for simplicity that there is a distinguished initial state $v_{0}$. Thus, given that we have access to a countably infinite set of hidden states, the HDP-HMM can be thought of as an HDP with an ever-shifting, countably infinite number of groups (metaphor: countably infinite tables in each of countably infinite restaurants, all sharing choices of dishes).

Last, as in the HDP, the HDP-HMM has hyperpriors on the hyperparameters $\alpha_{0}$ and $\gamma$, both gamma distributed with shape $a$. and inverse scale $b$. like so: $\alpha_{0} \sim \operatorname{Gamma}\left(a_{\alpha_{0}}, b_{\alpha_{0}}\right), \gamma \sim$ $\operatorname{Gamma}\left(a_{\gamma}, b_{\gamma}\right)$. To understand the effect of the settings of these hyper-hyperparameters, the reader should refer to the results (Chapter 5), where we vary the value of $b_{\gamma}$.

### 4.4.3 Applications

DPs, HDPs and HDP-HMMs are important statistical models to model grouped data and grouped data in time series. Their advantage lies in the fact that they are non-parametric techniques which
overcome the issue of fixing the model complexity prior to training. Some of the applications of these tools include document modeling (see Teh et al. (2006)), time series data prediction (see Alice in Wonderland example in Teh et al. (2006)), and clustering (next chapter). However, these models do come at a cost - efficient sampling techniques are required for inference in these models (Markov chain Monte Carlo schemes are used most often (see Neal (1998)). Finding efficient sampling techniques still remains an important research area.

## Chapter 5

## Experiments

In this chapter, we present the results of clustering using HDP-HMM on two well known gene expression time course datasets - Yeast sporulation dataset (Cho et al. (1998)) and Human fibroblasts dataset (Iyer et al. (1999)). Before we see the results, the datasets and the experimental set up are described.

### 5.1 Datasets

1. Iyer dataset - Iyer et al. (1999) recorded the response of human fibroblasts to serum, using cDNA microarrays representing about 8600 distinct human genes. Human fibroblasts require growth factors for proliferation, usually provided by fetal bovine serum (FBS). In the absence of growth factors, fibroblasts enter a state of low metabolic activity. Their study focused on the observing the activity of human fibroblasts when simulated with $10 \%$ FBS, preceded by 48 hours of serum deprivation. The expression levels of genes were measured at 12 times ranging from 15 min to 24 hours.

The dataset used in our experiments consists of 517 genes across 12 time points. The expressions were log-normalized and standardized to have $\log$ expression 1 at time $t=1$ for all genes. The genes are labeled as belonging to a cluster 1-10, with an additional 'outlier' cluster (labeled -1). We believe that the labels for this dataset were obtained by correlation analysis (Eisen et al. (1998)), followed by biology expert modification.
2. Cho dataset - Cell cycle is the orderly sequence of events by which a cell duplicates its contents and divides into two. It consists of mitosis (or division) and interphase. Cells experience important physiological changes during the cell cycle, and diverse biological events depend on maintenance of this periodicity. Loss of appropriate cell cycle regulation leads to genomic instability (Hartwell and Kastan (1994)). The study conducted by Cho et al. (1998) focuses on the mRNA transcript levels during the cell cycle of the budding yeast S.cerevisiae of more than 6000 genes.

The data used in our experiments is a subset of this dataset, consisting of 386 genes' expression values across 17 time points. The genes are labeled as belonging to cluster 1-5. The data was standardized prior to analysis.

### 5.2 Design

We compare our HDP-HMM to the standard hidden Markov model (with fixed number of hidden states) - which we refer to as 'finite HMM'. We also compare the HDP-HMM to the standard correlation analysis. In correlation analysis, as seen in the Chapter 3, the dissimilarity between a pair of genes is the inverse of correlation between the two time course 'vectors'. Hence, we define a similarity matrix, P , for the data as:

$$
\begin{equation*}
P=\left\{p_{c d}\right\}: \operatorname{Corr}(c, d) \tag{5.1}
\end{equation*}
$$

where $\operatorname{Corr}(c, d)$ is the correlation between the $c^{t h}$ and the $d^{\text {th }}$ time courses (as given in Chapter 3). $\left\{-p_{c d}\right\}$ is used as the dissimilarity measure in a hierarchical agglomerative clustering procedure to obtain a tree structure (more about the procedure later), which can be severed at a suitable point to obtain a clustering of the data.

In the finite HMM case, we define the probabilistic similarity measure between two genes as the probability that the time courses of each gene having identical hidden trajectories. This can be easily computed after an E step in the Baum-Welch algorithm. Let the posterior over the hidden state at time $t$ of the $c^{t h}$ gene sequence be $p\left(v_{t}^{(c)} \mid \boldsymbol{y}_{1: T}^{(c)}, \Theta\right)$, where $\Theta$ are the current parameters of
the HMM, then $\log P_{c d}$ is straightforwardly given by

$$
\begin{equation*}
\sum_{t=1}^{T} \log \sum_{r=1}^{k} p\left(v_{t}^{(c)}=r \mid \boldsymbol{y}_{1: T}^{(c)}, \Theta\right) p\left(v_{t}^{(d)}=r \mid \boldsymbol{y}_{1: T}^{(d)}, \Theta\right) \tag{5.2}
\end{equation*}
$$

The quantity, $P_{c d}$, measures the probability of two genes, $c$ and $d$, having traversed similar hidden trajectories. Hence, $-\log P_{c d}$ is used as a measure of dissimilarity between genes $c$ and $d$.

An analogous measure of similarity for HDP-HMM can be computed from the posterior distribution over hidden state trajectories - which, in the case of an infinite model is a set of samples. The similarity measure can be calculated simply from an empirical computation over the samples of trajectories taken over very long MCMC runs. Despite the countably infinite state space of HDP-HMM, the posterior samples always consist of represented hidden states, making this empirical computation simple. A similar method is used in the (i.i.d.) clustering using infinite mixture of Gaussians work of Rasmussen (2000) and Wild et al. (2002), but here we have extended to be a measure of similarity over sequences.

Note that the metric computed by (5.2) is approximate in the sense that, by taking the product of probabilities at each time point we are 'discarding' the temporal order - but the reader should realize that the quantities which are being multiplied themselves are obtained considering the temporal aspect of data. However, to go a step further and use the exact metric (as against the approximate metric above), we also tried using the following formulation of $P_{c d}$ (omitting the subscript ${ }_{\cdot 1: T}$ for brevity):

$$
\begin{align*}
p\left(\boldsymbol{v}^{(c)}=\boldsymbol{v}^{(d)} \mid \boldsymbol{y}^{(c)}, \boldsymbol{y}^{(d)}\right) & =\sum_{v} p\left(\boldsymbol{v}^{(c)}=v \mid \boldsymbol{y}^{(c)}\right) p\left(\boldsymbol{v}^{(d)}=v \mid \boldsymbol{y}^{(d)}\right)  \tag{i.i.d}\\
& =\sum_{v} \frac{p\left(\boldsymbol{y}^{(c)} \mid v\right) p(v)}{p\left(\boldsymbol{y}^{(c)}\right)} \cdot \frac{p\left(\boldsymbol{y}^{(d)} \mid v\right) p(v)}{p\left(\boldsymbol{y}^{(d)}\right)} \\
& =\frac{1}{p\left(\boldsymbol{y}^{(c)}\right) p\left(\boldsymbol{y}^{(d)}\right)} \sum_{v} p\left(\boldsymbol{y}^{(c)} \mid v\right) p\left(\boldsymbol{y}^{(d)} \mid v\right) p(v)^{2} \tag{5.3}
\end{align*}
$$

The normalization factor (on the left hand side of the sum), in the above equation, can be computed using the forward pass (one per observation sequence), while the expression within the sum can be calculated by a simple modification to the forward pass, in which we perform a paired
forward pass.
Once a dissimilarity measure matrix has been obtained from each of the above methods correlation, finite and infinite - the matrix is used in a hierarchical clustering procedure using 'average' linkage (see Chapter 2), to obtain a tree structure (called a dendrogram). The dendrogram can be severed at a suitable point to get a set of $C$ subtrees, and the leaves (time courses) of tree are labeled such that all leaves in the same subtree belong to the same cluster. The dendrogram also serves for visualization of the hierarchical clustering procedure.

### 5.3 Results

We compare the correlation analysis to finite HMMs with varying number of hidden states, $k=$ $1, \ldots, 40$, and HDP-HMM with several settings of its hyper-hyperparameters. For finite HMM, we ran experiments with 7 different seed values and averaged over the various scores. For HDP-HMM, the auxiliary variable Gibbs sampling consisted of 100,000 burnin samples, collecting 250 posterior samples thereafter having a spacing of 750 samples between each.

We present results in the form of tables, comparative plots of indices, and dendrograms. Most of the results presented here pertain to the Cho dataset. The Cho dataset, apart from having fewer genes, also has a fewer number of true clusters, which make it easy for visualization (in dendrograms).

1. Set 1 (Table 5.1): This result shows the effect of varying the hyper-hyperparameter, $b_{\gamma}$, setting for the HDP-HMM for the Iyer dataset with varying values of $C$.
2. Set 2 (Figure 5.1): This set consists of plots of indices for correlation analysis, finite HMM (all values of hidden states, $k=1, \ldots, 40$ ), and HDP-HMM (two values of the hyperhyperparameter $-b_{\gamma}=1$ and $b_{\gamma}=3$ ) for the Cho dataset.
3. Set 3 (Table 5.2): This set consists of index values in tabular form for both, Iyer and Cho, datasets. The index values presented are for correlation analysis, finite HMM ( $k=$ $1, \ldots, 40$, both exact and finite methods of computing distances) and HDP-HMM ( $b_{\gamma}=$ $0.25,0.5,1,2,3,4,5)$.

Figure 5.1: Comparative plot of indices with varying values of $k$ for finite HMM, and two values of hyperhyperparameter settings for HDP-HMM - with index values on y -axis and values of k along x -axis

Table 5.1: Choice of number of clusters, $C$, for Iyer data.

| 15 | 0.80 | 0.39 | 0.35 | 0.41 | 0.69 |
| 20 | 0.80 | 0.39 | 0.35 | 0.42 | 0.67 |

4. Set 4 (Figures 5.2 and 5.3 ): This set consists of dendrograms for correlation analysis, finite $\operatorname{HMM}(k=5,10,20,30,40)$ and HDP-HMM $\left(b_{\gamma}=0.25,0.5,1,2,3,4\right)$.
5. Set 5 (Figure 5.4): This set consists of dendrograms for finite HMM, using the two methods to compute probabilistic similarity metric, exact and approximate for values of $k=2,5,10$.

### 5.4 Interpretation

As Table 5.1 shows, the effect of varying the hyper-hyperparameter setting, for the HDP-HMM, is very small. This indicates that at this level of Bayesian hierarchy the settings of priors do not influence the learning of the model significantly - as it should be. This is in contrast to the scores obtained for finite HMM with varying values of $k$. In the latter case, we see that the scores vary considerably when the number of hidden states varies - evident from Table 5.2 and Figure 5.1 (as we scan across the x-axis). In other words, fixing the priors for a hierarchical non-parametric model does not constrain the model - but only encapsulates our belief of the underlying distribution of the data, as against a parametric model where it directly affects the learnt model.

From the plot of indices in Figure 5.1 it is clear that HDP-HMM performs as good as (and better than, in most cases) finite HMM and correlation analysis. Also, finite HMM shows signs of overfitting in crand and jaccard indices, when the scores taper down with increasing values of $k$. Another trend we note is that correlation analysis performs well on external indices - agreement

Table 5.2: Effect of varying the complexity $k$ of the finite models, and the hyper-hyperparameter $b_{\gamma}$.

(e) Infinite $b_{\gamma}=3$

(b) Infinite $b_{\gamma}=0.5$

(d) Infinite $b_{\gamma}=2$

(f) Infinite $b_{\gamma}=4$

Figure 5.3: Dendrogams for various settings of hyper-hyperparameters for HDP-HMM

Figure 5.4: Dendrogams for finite HMM with 2 different methods to compute similarity - approximate and exact - with $\mathrm{k}=2,5,10$
with ground truth - which is because the source of labels is correlation analysis (with biology expert modification).

It is clear from Table 5.2 that most of the winning entries are the HDP-HMM ones - which shows the clear edge non-parametric methods have over parametric methods. These results shows that a statistical framework such as HDP-HMM can solve clustering tasks such as the one presented effectively without overfitting. One of the interesting things about the table is performance of finite HMM with exact measure of similarity for Cho dataset. The reason behind some of the 'poor scores' is not very clear, but intuition points to sparsity of the data in very large parameter space or overfitting.

The dendrograms in Figures 5.2 and 5.3 show that most of the agglomeration in the case of HDP-HMMs happen at a much lower level than most of the finite HMM dendrograms, which indicates cleaner, well formed clusters in the case of HDP-HMM. Another point worth noting is that the change across the dendrogram shapes for various settings of hyper-hyperparameters is small - which again shows that the settings of priors do not influence the learnt model.

The dendrograms for finite HMM, exact metric and approximate metric, in Figure 5.4 are very similar. This observation combined with the values in Table 5.2 leads us to believe that both methods give similar probabilistic measures for similarity of two time courses.

## Chapter 6

## Conclusion

In this thesis we have seen the importance of the problem - namely, clustering gene expression timecourse data. As biologists probe deeper into nature of organisms, a fundamental understanding of cell, its constituents, and its activities is ever so important. To this end, deciphering the human genome has been a prime area of research for the last couple of decades and will continue to remain so for a long period of time to come, and clustering genes is one of key areas of research in bioinformatics. Machine learning and computational biology are two very useful tools used by bioinformatics' researchers in solving problems related to human genome.

Our solution to the above problem involves state of the art Bayesian approach to clustering - application of HDP-HMM to gene expression time-course clustering. By setting the traditional hidden Markov model in a hierarchical framework we are able to get around the model selection issue, and at the same time, by having a Dirichlet process in a hierarchical setting, we have made the state space of the HMM countably infinite. In short, we are able to address both the shortcomings of earlier methods like correlation analysis (discarding time aspect of the data) and finite HMMs (fixing model complexity beforehand).

We believe that we have successfully shown the applicability of HDP-HMM to gene clustering. However, having said this, we feel that there are still a few issues we need to address and few areas we need to explore further in order to firmly establish HDP-HMM's suitability to such tasks.

### 6.1 Future directions

Some of the areas need further exploration. Prime among those are leave-one-out analysis. It would be interesting remove a gene from the training set, and learn the model. Once learnt, the predictive density on the unseen time course can be calculated and this could be an indicator of how well the data is modeled. Another approach, apart from predictive density, is to classify the unseen data point as belonging to one of the $C$ clusters.

The other area that we would like to explore is applying the model to different datasets and synthetic datasets. Synthetic time series datasets can be produced using sine functions with suitable noise added, with time points chosen at regular intervals, starting at some random point. Another method to generate synthetic dataset is using spline equations with suitable noise. An advantage of using synthetic data is availability of huge quantities of labeled data, using which we can the determine the scalability of models as both, number of time courses as well as number of time points increase. Another advantage being the ability to tweak the dataset to test the various aspects of our models like missing data and unequally spaced time points.

It would also be interesting to compare our model to other models and methods. One of them being CAGED, a publicly available clustering package, exclusively aimed at clustering gene expression time courses. Another statistical time series model that would make an interesting comparison would be a Bayesian HMM. HDP-HMM is Bayesian by construction - we integrate of the $G_{j}$ 's at the group level (remember the Chinese restaurant process and Chinese restaurant franchise metaphors). However, a finite HMM trained using the Baum-Welch algorithm gives the ML estimates of the parameters $(\boldsymbol{A}, \boldsymbol{C}$, and $\boldsymbol{\pi})$. In order to obtain a Bayesian version of a finite HMM, we can incorporate a prior over these parameters and integrate over the prior.

Sampling based exact metric for HDP-HMM: At present we do not have a way to compute the exact metric for the infinite HMM, as we do for the finite HMM (5.3); it is possible however to compute a stochastic estimate of the probability in (5.3) by sampling many finite instantiations of the HDP-HMM, each of which have a fixed number of hidden states and associated point parameters. The measures of dissimilarity for each sampled finite HMM can then be computed and averaged. This is a computationally expensive solution for the infinite model, but at present is the
only available algorithm to compute this metric.
Despite the areas for further exploration mentioned above, we consider the study done as a part of this thesis points to the success of HDP-HMM (and non-parametric Bayesian methods in general) to complex statistical modeling tasks. Moreover, we have addressed an important issue in bioinformatics and have provided a novel way to approach problems in bioinformatics.

## Appendix A

## Dirichlet Process theory

Theorem 1: If $G \sim D P\left(\alpha, G_{0}\right)$ and $\theta_{1} \in \Theta$ is a sample from $G$, then

$$
\begin{equation*}
G \mid \theta_{1} \sim D P\left(\alpha G_{0}+\delta_{\theta_{1}}\right) \tag{A.1}
\end{equation*}
$$

where $\delta_{\theta_{1}}$ is a point mass at $\theta_{1}$

Proof: Consider some natural number $k$ and partition $B$. From the definition of a Dirichlet Process, we know that

$$
\left(G\left(\Theta \in B_{1}\right), G\left(\Theta \in B_{2}\right), \ldots, G\left(\Theta \in B_{k}\right)\right) \quad \sim \operatorname{Dir}\left(\alpha G_{0}\left(B_{1}\right), \alpha G_{0}\left(B_{2}\right), \ldots, \alpha G_{0}\left(B_{k}\right)\right)
$$

Also, we know that given a fixed value of $k$ and a fixed partition $B, G$ is distributed as a Dirichlet distribution and the sample $\phi_{1}$ is an observation from a single trial. Hence, from the posterior for Dirichlet distribution, we have

$$
\left(G\left(\Theta \in B_{1}\right), \ldots, G\left(\Theta \in B_{k}\right)\right) \mid \theta_{1} \sim \operatorname{Dir}\left(\alpha G_{0}\left(B_{1}\right)+\delta_{\theta_{1}}\left(B_{1}\right), \ldots, \alpha G_{0}\left(B_{k}\right)+\delta_{\theta_{1}}\left(B_{k}\right)\right)
$$

The above will hold for all $k$ and all partitions $B$ that might be chosen. Hence,

$$
G \mid \theta_{1} \sim D P\left(\alpha G_{0}+\delta_{\theta_{1}}\right)
$$

Theorem 2: The marginal probability

$$
\begin{equation*}
P\left(\Theta \in B_{i}\right)=G_{0}\left(B_{i}\right) \tag{A.2}
\end{equation*}
$$

## Proof:

$$
\begin{aligned}
P\left(\Theta \in B_{i}\right) & =\int_{G} d G P\left(\Theta \in B_{i} \mid G\right) P(G) \\
& =\int_{G} d G G\left(\Theta \in B_{i}\right) P(G) \\
& =E\left[G\left(\Theta \in B_{i}\right)\right]
\end{aligned}
$$

From Definition 1, since

$$
\left(G\left(\Theta \in B_{1}\right), G\left(\Theta \in B_{2}\right), \ldots, G\left(\Theta \in B_{k}\right)\right) \quad \sim \operatorname{Dir}\left(\alpha G_{0}\left(B_{1}\right), \alpha G_{0}\left(B_{2}\right), \ldots, \alpha G_{0}\left(B_{k}\right)\right)
$$

and from definition of Dirichlet distribution, we can write

$$
\begin{aligned}
P\left(\Theta \in B_{i}\right) & =E\left[G\left(\Theta \in B_{i}\right)\right] \\
& =\frac{\alpha G_{0}\left(B_{i}\right)}{\sum_{j=1}^{k} \alpha G_{0}\left(B_{j}\right)} \\
& =\frac{\alpha G_{0}\left(B_{i}\right)}{\alpha} \\
& =G_{0}\left(B_{i}\right)
\end{aligned}
$$

Consider how the above marginal probability of $\Theta \in B_{i}$ changes under the posterior of $G$ after
$\theta_{1}$ has been sampled:

$$
\begin{align*}
P\left(\Theta \in B_{i} \mid \theta_{1}\right) & \left.=E\left[G\left(\Theta \in B_{i}\right) \mid \theta_{1}\right)\right] \\
& =\frac{\alpha G_{0}\left(B_{i}\right)+\delta_{\theta_{1}}\left(B_{i}\right)}{\sum_{j=1}^{k} \alpha G_{0}\left(B_{j}\right)+\delta_{\theta_{1}}\left(B_{j}\right)} \\
& =\frac{\alpha G_{0}\left(B_{i}\right)+\delta_{\theta_{1}}\left(B_{i}\right)}{\alpha+1} \tag{A.3}
\end{align*}
$$

The above leads to what is known as the 'clustering effect'. Consider the case when $k=2$ and $B_{1}=\left\{\theta_{1}\right\}$ and $B_{2}=\left\{\theta: \theta \neq \theta_{1}\right\}$. Since $\Theta$ is a continuous random variable, under the prior $D P\left(\alpha G_{0}\right)$ we have

$$
\begin{aligned}
P\left(\Theta=\theta_{1}\right) & =G_{0}\left(\left\{\theta_{1}\right\}\right) \\
& =0
\end{aligned}
$$

Under the posterior $D P\left(\alpha G_{0}+\delta_{\theta_{1}}\right)$ after having sampled $\theta_{1}$ however,

$$
\begin{align*}
\left(G\left(\Theta=\theta_{1}\right), G\left(\Theta \neq \theta_{1}\right)\right) \mid \theta_{1} & \sim \operatorname{Dir}\left(\alpha G_{0}\left(\left\{\theta_{1}\right\}\right)+\delta_{\theta_{1}}\left(\left\{\theta_{1}\right\}\right), \alpha G_{0}\left(\left\{\theta: \theta \neq \theta_{1}\right\}\right)+\delta_{\theta_{1}}\left(\left\{\theta: \theta \neq \theta_{1}\right\}\right)\right. \\
& \sim \operatorname{Dir}(1, \alpha) \tag{A.4}
\end{align*}
$$

Therefore, under the posterior $D P\left(\alpha G_{0}+\delta_{\theta_{1}}\right)$ after having sampled $\theta_{1}$, the probability of sampling the same point has a non-zero probability. Thus,

$$
\begin{align*}
& P\left(\Theta=\theta_{1}\right)=\frac{1}{\alpha+1}  \tag{A.5}\\
& P\left(\Theta \neq \theta_{1}\right)=\frac{\alpha}{\alpha+1} \tag{A.6}
\end{align*}
$$

Now, extending to the case where we have $n$ samples of $\boldsymbol{\theta}=\theta_{1}, \ldots, \theta_{n}$, we can write the marginal
probability of $\Theta \in B_{i}$ under the posterior DP as

$$
\begin{align*}
P\left(\Theta \in B_{i} \mid \theta_{1}, \ldots, \theta_{n}\right) & \left.=E\left[G\left(\Theta \in B_{i}\right) \mid \theta_{1}, \ldots, \theta_{n}\right)\right]  \tag{A.7}\\
& =\frac{\alpha G_{0}\left(B_{i}\right)+\delta_{\theta_{1}}\left(B_{i}\right)+\ldots+\delta_{\theta_{n}}\left(B_{i}\right)}{\sum_{j=1}^{k} \alpha G_{0}\left(B_{j}\right)+\delta_{\theta_{1}}\left(B_{j}\right)+\ldots+\delta_{\theta_{n}}\left(B_{j}\right)} \\
& =\frac{\alpha}{\alpha+n} G_{0}\left(B_{i}\right)+\frac{1}{\alpha+n} \sum_{i=1}^{n} \delta_{\theta_{i}}\left(B_{i}\right) \tag{A.8}
\end{align*}
$$

The random probability vector under the posterior DP is

$$
\begin{align*}
(G(\Theta \in \boldsymbol{\theta}), G(\Theta \notin \boldsymbol{\theta})) \mid \boldsymbol{\theta} & \sim \operatorname{Dir}\left(\alpha G_{0}(\boldsymbol{\theta})+\sum_{j=1}^{n} \delta_{\theta_{j}}(\boldsymbol{\theta}), \alpha G_{0}(\{\theta: \theta \notin \boldsymbol{\theta}\})+\sum_{j=1}^{n} \delta_{\theta_{j}}(\{\theta: \theta \notin \boldsymbol{\theta}\})\right) \\
& \sim \operatorname{Dir}\left(\sum_{j=1}^{n} \delta_{\theta_{j}}(\boldsymbol{\theta}), \alpha\right) \tag{A.9}
\end{align*}
$$

Therefore under this posterior, the marginal probabilities (that is, integrating out G) of sampling one of the already chosen $\boldsymbol{\theta}$ for the $(n+1)^{t h}$ sample and the probability of choosing a distinct sample are given by:

$$
\begin{align*}
& P\left(\theta_{n+1}=\theta_{i} \text { for } 1 \leq i \leq n \mid \theta_{1}, \ldots, \theta_{n}, \alpha, G_{0}\right)=\frac{1}{\alpha+n} \sum_{j=1}^{n} \delta_{\theta_{j}}\left(\theta_{n+1}\right)  \tag{A.10}\\
& P\left(\theta_{n+1} \neq \theta_{i} \text { for } 1 \leq i \leq n \mid \theta_{1}, \ldots, \theta_{n}, \alpha, G_{0}\right)=\frac{\alpha}{\alpha+n} \tag{A.11}
\end{align*}
$$

Let us define an indicator variable $W_{n}$ to be 1 if $\theta_{n}$ is distinct and $W_{n}=0$ otherwise. If $N(\Theta)=\sum_{i=1}^{n} W_{i}$, then the expected number of distinct samples is

$$
\begin{equation*}
E[N]=\alpha \sum_{i=1}^{n} \frac{1}{\alpha+i-1} \tag{A.12}
\end{equation*}
$$

Thus from (A.11) and (A.12) above we see that the probability of observing a distinct sample goes to 0 as $n \rightarrow \infty$ and at the same time, the expected number of distinct samples goes to $\infty$ as $n \rightarrow \infty$. This illustrates the clustering effect.

## The interpretation of $\alpha$ and $G_{0}$

From (A.7) and (A.8), we know that

$$
E\left[G \mid \theta_{1}, \ldots, \theta_{n}\right]=\frac{\alpha}{\alpha+n} G_{0}+\frac{1}{\alpha+n} \sum_{i=1}^{n} \delta_{\theta_{i}}
$$

We can interpret $\alpha$ to be a 'control knob' that controls how closely our draw $G$ follows $G_{0}$. Thus, as $\alpha$ grows larger, the contribution from the first term of (A.8) increases while that of the second decreases, and as $\alpha$ gets smaller, the opposite happens. Thus, $G_{0}$ can be interpreted as a prior over $\Theta$.

Definition 2: An infinite set of random variables are said to be infinitely exchangeable if for every finite subset $\left\{x_{1}, \ldots, x_{n}\right\}$ we have,

$$
\begin{equation*}
P\left(x_{1}, \ldots, x_{n}\right)=P\left(x_{\pi(1)}, \ldots, x_{\pi(n)}\right) \tag{A.13}
\end{equation*}
$$

for any permutation $\boldsymbol{\pi}$.

Theorem 3 (deFinetti (1973)) : A set of random variables is infinitely exchangeable if and only if

$$
\begin{equation*}
P\left(x_{1}, \ldots, x_{n}\right)=\int d P(\theta) \prod_{i=1}^{n} P\left(x_{i} \mid \theta\right) \tag{A.14}
\end{equation*}
$$

for some $\theta$ and some measure $P(\theta)$.
The graphical model representing exchangeability is shown in Figure A.1.

Figure A.1: Graphical Model representing Exchangeability
