Abstract— In contrast to the traditional wireless sensor network (WSN) applications that perform only data collection and aggregation, new generation of information processing applications, such as pursuit-evasion games, tracking, evacuation, and disaster relief applications, require in-network information storage and querying. Due to the resource limitations of WSNs, it is challenging to implement in-network information storage and querying in a resilient, energy-efficient, and distributed manner. To address these challenges, we exploit location information and geometry of the network and present an in-network querying infrastructure, namely distributed quad-tree (DQT) structure. DQT satisfies efficient in-network information storage as well as distance-sensitive querying: the cost of answering a query for an event is at most a constant factor (in our case $2\sqrt{2}$) of the distance “d” to the nearest event in the network. DQT construction is local and does not require any communication. Moreover, due to its minimalist infrastructure and stateless nature, DQT shows graceful resilience to the face of failures.

Keywords: *Distance Sensitive In-network Querying, Spatial Querying, Distributed Quad-tree, Wireless Sensor Networks, GPSR*

I. INTRODUCTION

Traditionally wireless sensor networks (WSNs) have been treated mostly as data collection and aggregation networks. Examples of these include WSNs deployed for environmental monitoring [19][22] and military surveillance [1][2]. However, as the WSN technology matured, WSNs started to serve more as active information processing tools instead of passive information gathering mechanisms. Examples of these information processing WSNs include pursuer-evader applications [4][20], evacuation applications [3] etc., where mobile entities query the WSN on the spot to learn about their surroundings. Latency and energy-efficiency suffer drastically if these queries are always routed over multiple hops to a centralized base station for resolution. Thus, in-network information storage and querying techniques, such as data centric storage [21] and geometric hash functions [18] have been developed to address these issues.

While in-network querying alleviates the latency and energy-efficiency concerns of information processing WSN applications, certain requirements need to be satisfied by the in-network querying service to be deployable in practice. Firstly, the in-network querying service needs to be

distance-sensitive for querying and also efficient for information storage. Distance-sensitivity for querying implies that the cost of answering a query for an event should be at most a constant factor “s” of the distance “d” to the nearest event in the network. Efficient information storage for events implies that the cost of advertising event information is at most a constant factor of the diameter “D” of the network. It is challenging to satisfy both properties simultaneously, since the querying node and the event source are unaware of each other’s location and straightforward techniques satisfy one of the properties to the extent of violating the other. For example, directed diffusion [14] chooses to optimize the information storage ($O(1)$ cost) to the extent of querying ($O(d^2)$ cost). Combs & needles optimizes querying, $O(1)$, to the extent of information storage $O(D^2)$.

Secondly, to be deployable in practice, the in-network querying service should require minimal infrastructure and its construction should be low cost. In-network querying structures that require costly bottom-up constructions are impractical and error-prone since flooding based constructions are susceptible to severe message losses due to collisions, and may even bring the entire network to a grinding halt. Experimental work found that message loss due to burst of collisions may amount to 50% of total traffic [1][2]. Furthermore, querying structures that employ an elaborate structure may require high maintenance costs due to node failures.

Finally, the in-network querying service should provide graceful resilience to the face of node failures. By graceful resilience, we mean that the performance degradation of querying should be commensurate with the severity of faults. That is, single mote (a WSN node [1]) failure should not impact the performance of querying, the failure of large areas of nodes may impact the performance only proportional to the diameter of the resultant hole in the network and the functionality of querying should be preserved unless the network is partitioned. **Contributions and overview:** We present an in-network querying infrastructure, namely Distributed Quad-Tree (DQT) structure, which satisfies all the requirements above and is suitable for real-world WSN deployments.

DQT overlays quad-tree structure on WSN and satisfies distance-sensitive in-network querying as well as efficient information storage. The motivation for using quad-trees for in-network querying in WSN comes from the extensive use of quad-trees [8] in centralized algorithms domains especially in

the computational geometry area. Quad-tree partitions the image into recursively four quadrants, where each node (except leaf nodes) has four children. Due to the hierarchical construction, the image can be stored at different layers with more refined resolution at lower layers. Here, for our DQT construction, we overlay a quad-tree in a distributed manner on WSNs as we discuss in Section 5.

DQT maintains a minimalist structure, and in fact, DQT can be considered as stateless. DQT achieves this feat by employing an encoding technique that maps a quad-tree over the deployment area. Just by using the location information at a mote and the coordinates of the top-left and bottom-right corners of the deployment area, our encoding maps a WSN mote to the corresponding level 1 box address. A level 1 box is a smallest partition area in DQT. The addresses of the clusterhead and neighboring clusterheads at each level for a given node are easily derivable arithmetically using the node's DQT address. The implication is that the construction of DQT is local and does not require any communication at all. By exploiting the location information we avoid a costly bottom-up construction.

In our DQT embedding, we choose clusterheads at each level to be the ones closest to the base station at the center of the network rather than the ones closest to the center of the box at that level. Note that selecting the clusterheads to be the center of each level box results in backward links, and suboptimal paths while going to the clusterheads at higher levels. Our use of geometry in selecting clusterheads ensures that there are no backward links during the querying and advertise operations. The encoding and DQT structure construction is discussed in Section 4.

The stateless operation of DQT makes it resilient to the face of node failures and topology changes. To achieve resiliency while routing to clusterheads or neighbors in the structure, DQT maps the DQT address of the destination to the physical coordinates, and leverages on the resilience of a geographic routing scheme (such as GPSR) [16] for delivering the message. Since mote failures do not often lead to failure of a level 1 box, single node failures do not affect the performance of DQT. In the case of failures of motes in an area, GPSR delivers a message addressed to a box in that area to a mote on the boundary of the hole. Since DQT is stateless, the recipient mote easily acts as a proxy on behalf of the intended destination box, and determine the next step in the query or advertise operation by simply plugging the destination box id (instead of its own box id) into the corresponding procedures for the DQT operation. This way, failures of motes in an area degrade the performance of DQT operations proportional to the size of the area. Essentially, the degradation is equal to that of routing stretch in GPSR due to the holes. DQT preserves correct functionality unless the network is partitioned, and even then, functionality is satisfied within each partition. We discuss the resilience of DQT in Section 6.

Our simulation results using ns2 serve as empirical

validation of scalability, distance-sensitivity, and resilience of DQT. We present our simulation results in Section 7.

II. RELATED WORK

Centralized querying has been the common mode of querying in WSN. For this mode of operation, the base station acts as the point where the query is introduced and results are gathered. For example, in TinyDB [17], queries are first parsed at the base station and disseminated into the WSN to be executed. This centralized structure may not be feasible for distributed and self-organizing sensor networks since: (1) such a base station may not exist, (2) for in-network queries, a query may be introduced from any node in the network and propagating the query to the base station is costly.

Geographic Hash Tables (GHT) [18] gives a simple solution for in-network querying problem: GHT stores and retrieves information by using a geographic hash function on the type of the information. GHT can hash event information far away from the nearby query nodes, and thus violate the distance sensitivity of querying. The average cost of GHT is $D/3$ according to [5], where D is the diameter of the network. Although hierarchical version of GHT alleviates this problem, the problem cannot be solved entirely. DQT structure improves over GHT by providing distance sensitive querying.

To support efficient in-network queries and to store the indices of data, some sort of hierarchy seems beneficial. Here the idea is to push the query to the higher levels until it is resolved at some level. The query then traverses the subtree to get relevant information. Distance Sensitive Information Brokerage (DSIB) protocol [9] achieves distance-sensitivity in a hierarchically partitioned network by using a push-based approach: an event advertises to neighbors as well as its parents at every level of the hierarchy. DSIB does not require localization information and relies purely on communication topology. To this end, DSIB introduces a costly bottom-up construction and a special purpose routing algorithm. In contrast to DSIB, DQT assumes localization information and in turn is able to provide an efficient local construction. Use of localization information is not impractical via GPS or other localization techniques. Real-world WSN deployments such as Lites [1] and Exscal [2] already utilize localization information in their construction. Also, DQT relies on the resiliency of the GPSR rather than introducing a routing algorithm.

DIFS [10] considers arbitrary and complex queries, and extends traditional binary-tree and quad-tree by allowing multiple parents and multiple roots. DIFS is susceptible to the distance sensitivity problem: a node may have several parents, some of which maybe located far away. Thus constructing the DIFS structure and update operations are expensive. This is the price DIFS pays to handle arbitrary complex queries about sensor values rather than just binary event information as we focus on in DQT.

DIMENSIONS [23] system provides a unified view of data processing and in-network querying in WSNs. Similar to our scheme, clusterheads are elected to be on the path to the base station in DIMENSIONS; straight-line intersection and geometric calculation are used to this end. Compared to DIMENSIONS, DQT provides a more robust and lightweight method for electing the clusterheads (Section 4). Moreover, instead of simply copying data to multiple places for handling fault tolerance, DQT achieves resilience by exploiting GSPR routing and stateless nature of the hierarchical structure without sacrificing much flexibility and space.

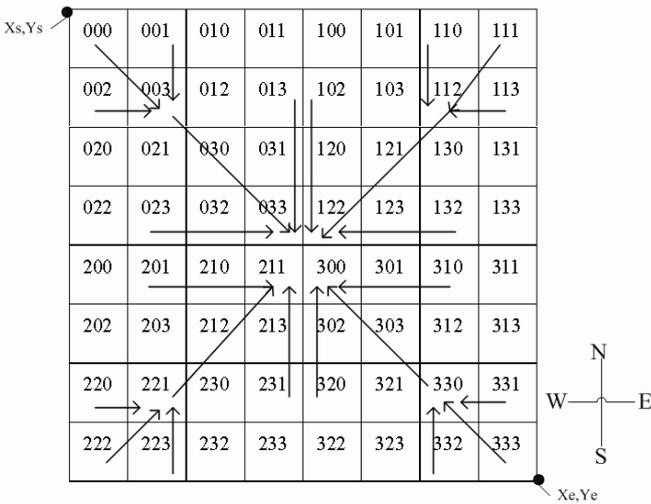

III. MODEL

We assume that the WSN nodes sit on a two dimensional plane and their coordinates (x,y) are made available to themselves.¹ We assume a connected network and availability of geographic routing such as greedy perimeter stateless routing (GPSR) [16] or CLDP [15]. There may exist some coverage holes in the network, but no partitions (i.e., isolated regions). Our analytical results for DQT are proved in Section V in the absence of holes in the network, and in Section VII via simulations we show how they hold up in the presence of holes in the network.

As we describe in the next section, the network is divided into grid cells while embedding a DQT over the network. A level 1 box in DQT constitutes the smallest cell area in the DQT structure. We assume that all nodes inside a level 1 box are within one hop distance. In our terminology, a node refers to a physical WSN node, while a “node” refers to a virtual DQT node, such a level 1 box.

The cost of querying an event is measured as the number of hops traveled from the querying node to a node that holds an advertisement about the event.

IV. DQT STRUCTURE AND CONSTRUCTION

¹ Extension of DQT structure to 3D is straightforward

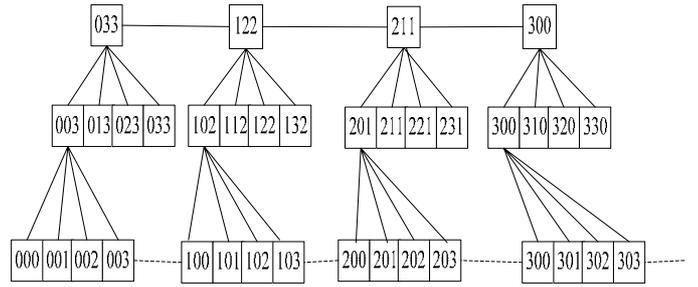

Figure 1, Node addressing and tree structure

For constructing DQT, we employ an encoding trick first presented in [11]. In this encoding, each level 1 box in the structure is assigned an ID which uniquely identifies a region. The length of the ID is equal to the number of levels. We use this addressing scheme to preserve the location information of a node. Due to the way we construct level 1 boxes, this scheme is independent of the number of nodes, but relies on the partition levels. Fig.1 illustrates the addresses of the nodes in a region with 3 levels.

Similar to the centralized quad-tree, DQT is a hierarchical structure. In each level of partition, a node is assigned as clusterhead node of the region. The clusterhead is always its own child in lower levels. The clusterhead at each level partition is statically assigned to be closest node to the geographic center point of the entire network. For example, in level 1 partition, node 003 is selected as clusterhead for 00 region, because it is closer to center than nodes 000, 001 and 002. Similarly, node 033 is selected as level 2 clusterhead, as it is closer to the center than level 2 nodes 003, 013, and 023. Hence, the node closest to the center of the entire network in each subpartition is selected as the parent node of that subpartition. The benefit of such a selection is to avoid backward links. For example, in Fig.1, node 000 propagates the query to its root node 033 by first contacting parent node 003, then 003’s parent 033. A short path is achieved since there is no backward link on the querying path. A DQT node may belong to different levels in the hierarchy depending on its location. If a node is a member at level k , it is also a member at all levels less than k . We denote a node p ’s parent as $p.parent$ and children as $p.child$. The neighboring nodes are called siblings, which are denoted as $p.sibling$.

This structure is quite simple and adapts to multi-dimensional sensor readings, such as (temp, light, humidity), since the construction of DQT is not related to the sensor value. Another difference between DQT and the centralized quad-tree is that DQT does not need a root of the tree. The four nodes in the top level function as the root.

4.1. Mapping from localization to DQT addressing

Each node in DQT can calculate the DQT address of the level 1 partition it resides in from its x,y coordinates easily. Let (x_s, y_s) at NW and (x_e, y_e) at SE be the two endpoints of the area

where DQT should be overlayed. Assume DQT have i levels. The area of each level 1 box of partition is $w * l$, where width $w = (y_e - y_s) / 2^i$ and length $l = (x_e - x_s) / 2^i$. Then DQT address of a node (x, y) can be calculated as:

$$DQT_addr = \left[\left\lfloor \frac{(x - x_s)}{w} \right\rfloor \pmod{2} \right] + \left[\left\lfloor \frac{(y - y_s)}{l} \right\rfloor \pmod{2} \right] * 2$$

The mapping calculates the X and Y address separately, and then adds them together. We can verify this from Fig. 1, for instance, node ID 033 is obtained by adding 011 and 022, and node ID 332 is obtained by adding 110 and 222. The reason that the second term in the DQT address calculation is multiplied by 2 is because the Y addresses pace by 2 for every increment in DQT addressing scheme. Given this mapping, any node can locally compute its DQT address based on its coordinates (x, y) .

Besides the DQT address, each node also maintains its (x, y) coordinate address. This location information is used in GPSR routing in querying and advertising. Since GPSR routing only requires single hop information, which has already been cached as level one neighbors in our structure, it is quite simple to adapt to WSN. When the coverage has irregular holes, local optimal path can be reached using right hand rules in GPSR. By using the above encoding trick and assigning DQT addresses for DQT nodes, we can start constructing the DQT structure.

4.2 DQT Local Construction

DQT uses local construction instead of bottom-up construction to reduce communication cost during initial construction. A static and local scheme that uses the address of the box suffices for calculating every level clusterheads and neighbors. Each node may have neighbors at N, S, E, W, NE, NW, SE and SW. The following two methods can be used to find the clusterhead and neighbors at level i .

The {clusterhead validate} algorithm provides the relation of the DQT address to its clusterhead. We find that in NW region of the map, nodes with DQT-address “3” at level i and lower positions (denoted as $p.address(i_*)$) become the clusterheads at the corresponding level. Similarly, in NorthEast partition, nodes with DQT-address “2” at level i become the clusterheads. In Fig.2, $p.address(h)$ is the highest bit of the DQT-address, which determines the region of a node. This algorithm guarantees the clusterheads at each level are closer to the map center than any children (except for itself).

```

Procedure Cluster_head_Validate (node p, level i)
Switch (p.address(h))
Case 3: //p in SE region
    { If p.address(i_*) == 0, then return true; else return false }
Case 2: //p in SW region
    { If p.address(i_*) == 1, then return true, else return false }
Case 1: //p in NE region
    { If p.address(i_*) == 2, then return true, else return false }
Case 0: // p in NW region
    { If p.address(i_*) == 3, then return true, else return false }
    Figure 2 clusterhead validate algorithm

```

To find the neighbors, we again make use of the location information. We use node p and node q to represent the originator and its neighbor. First we use p 's location information and increase its coordinates x, y value by a level i box lateral length to find a neighbor node in each direction. If either of x or y value exceeds the range of the map, we ignore that neighbor. For each of these nodes, we find their level i clusterheads. These clusterheads are node p 's level i neighbors. For instance, given a node 201 at level 2, we can find its neighbor at north direction by following two steps: (1) Reduce Y value by a level two box length, then we can locate the node 021 through the new (x, y) coordinates; (2). Find the clusterhead for node 021 at level 2, which is 023. The detailed algorithm is in the technical report [6].

V. QUERYING IN DQT

Before discussing querying in detail, we discuss how events are indexed in DQT.

5.1 Indexing of event information

000 #	001 #	010 #	011 #	100	
002 #	003 #	012 #	013 ##	102	
020 #	021 #	030 #	031 #	120	
022 #	023 ##	032 #	033 ##	122	
200	201	210	211	300	

Figure 3, node 003's sibling structure

In any hierarchical structure as with DQT, some multi-level boundary nodes are far away from each other in the structure, while actually they are placed nearby in the network. High latency maybe introduced if the search follows the path of the tree structure strictly. For example in Fig.1, node 011 and 100 are neighbors. A query from node 011 to node 100 may route to higher level clusterheads such as node 013 and node 033. Our solution is to use sibling links to nearby intermediate nodes. A sibling link is the link between a node and its neighbors in each direction (so each may at most have 8 sibling neighbors). The sibling links only exist between nodes on the same level in the structure. Fig.3 illustrates the point of view of an intermediate node 003 in the distributed quad-tree structure. The nodes with “#” are level 1 sibling nodes, the nodes with “##” are level 2 sibling nodes. A node at level i maintains the event information of its cluster, as well as the event information of its neighbors.

When an event is detected at a level 1 node p , p contacts its immediate parent node at level 1. The parent node updates its record for that child. Node p also contacts its sibling nodes to update their records accordingly. Recursively, the update operation is executed till the top level. This is similar to the

information storage scheme discussed in [9] and the sibling links in Stalk [7].

5.2 Nearest Neighbor query

Nearest Neighbor (NN) query is defined as, finding the data object which is closest to the querying object given a set of objects. The classic NN query returns exactly one object as a result. In WSNs, a query can be started at any location. The initiator of a query is the node where the query is entered into the system. The query point is the node for which we want to get NN query result. Query point by default is the same node as initiator of query but it may be specified to be any point in the network.

Our algorithm prevents the propagation of searching to higher levels if it can be answered locally. Through taking advantage of the spatiality information, both the query efficiency and latency is greatly improved. Our query strategy is to start the query at the query point using local information because the node may belong to multiple levels and therefore hold multi-layer information locally. If no result is obtained, the query is propagated to the parent recursively. At some level the event information is reached, the query is then stopped and returned to the originator.

What if the query point is at another location? That means the initiator of the query and the query point belong to two different nodes. First the query is passed to the query point from the initiator of the query using GPSR routing scheme, and then this querying process is started from the query point. The following results are in the absence of faults. In the simulation section, we talk about the results in the presence of faults.

Lemma 1. *A DQT node at level i stores $O(i)$ information.*

Proof. A node at level i is clusterhead from level 1 to i along the path. The number of neighbor nodes at each level is less than or equal to eight. Therefore the node needs $9 \cdot i$ (including one record for its subtree) space and stores $O(i)$ information.

Theorem 1. *The total space needed for the construction of distributed quad-tree is less than $12 \cdot b$, where b is the total number of level 1 nodes.*

Proof: According to Lemma 1, level 1 nodes use up $9 \cdot b$ space. Similarly, all level 2 nodes total to a $9 \cdot b/4$ space usage. Thus, the total space needed for constructing the distributed quad-tree is:

$$9 \cdot \left(b + \frac{b}{4} + \frac{b}{4^2} + \dots + 1 \right) = 12 \cdot b \left(1 - \frac{1}{b} \right) < 12b$$

Lemma 2. *The distance between a level i node and its neighbors is at most $2^i \cdot \sqrt{2}$ hops.ⁱⁱ*

Proof: According to the partition rule of quad-tree, a level i node is the clusterhead of a $2^i \cdot 2^i$ area. The distance between a level i node and its neighbors is either 2^i (for N, S, E, W neighbors) or $2^i \cdot \sqrt{2}$ (for NE, NW, SE, SW neighbors) depending on the direction. Since the clusterhead is one of its neighbors at level i , so the distance between a level i node and

ⁱⁱ The result is based on the assumption that width equals to length for each level 1 box.

its clusterhead is also less than $2^i \cdot \sqrt{2}$ hops, which is the diagonal distance of a level i partition.

Theorem 2. *The distance stretch factor s for spatial query in our structure is $2\sqrt{2}$ in worst case. In another words, an event d hops away can be achieved by the querying node within $d \cdot 2\sqrt{2}$ hops.*

Proof: A query from an intermediate level node does not constitute the worst case. The reason is that the clusterhead nodes holds multi-levels information locally and this local cache can be used to answer queries. So, let's consider a query from a bottom level node that reaches a level j clusterhead. We define the query cost as the number of hops from the query point to the node that holds the result.

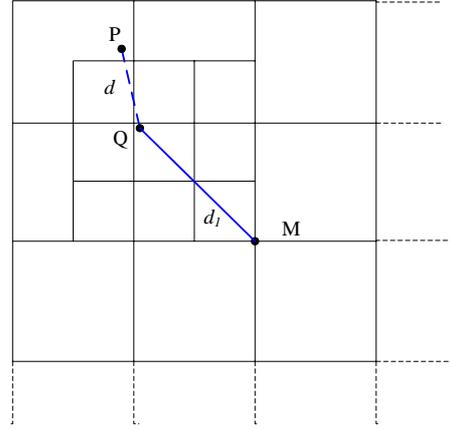

Figure 4. Distance stretch factor s analysis

In Fig.4, d_1 is the distance from querying node Q to highest level of node M that the query is propagated; d is the distance from Q to P , where P is the destination node that node Q is querying. Distance stretch factor s is defined as $s = d_1 / d$.

According Lemma 2, the distance from level $i-1$ node to its parent node (level i) is $2^{i-1} \cdot \sqrt{2}$ hops. Since the backward links are avoided in going-up phase, the total distance from level 1 to level j can be calculated as $(1+2^1+2^2+\dots+2^{j-1}) \cdot \sqrt{2}$, which is overall $d_1 = \sqrt{2} \cdot (2^j - 1)$ hops. Since P and Q are not $i-1$ level neighbors, the distance $d \geq 2^{j-1}$. The equivalence is true when P and Q are located exactly on the opposite borders of a level $i-1$ box. Hence:

$$s = d_1 / d \leq \sqrt{2} \cdot (2^j - 1) / 2^{j-1} < 2\sqrt{2}$$

Based on the result on case 1 and case 2 analyses, we conclude that our structure is distance sensitive with a distance stretch factor $2\sqrt{2}$.

VI. FAULT TOLERANCE

DQT is fault tolerant due to several aspects.

First, any leaf node failure is masked without causing any update operation and structure change. This is because, for a dense sensor network, each level 1 partition contains several nodes and all nodes in the same partition share a common DQT

ID. Moreover, since DQT structure is stateless, the nodes do not need to maintain a state of its own, they act on behalf of other nodes in the level 1 box.

Second, DQT can handle coverage holes nicely. Only if all the motes inside a level 1 partition fail (although this is unlikely to happen) a hole may be formed in DQT. Using the right hand rule, GPSR re-routes the information to the closest node to the target node, which we call the proxy node. The proxy node pretends to be the target node and finds its neighbors through local computation. Then it follows the NN searching algorithm in Fig.2. Change of the shape of a hole only changes the selection of proxy nodes, and has little influence on other nodes.

Failures may cause the following two cases. Case 1: Failures happen before the event advertisement. When a target node of event advertisement fails, the event is published to proxy node by default, which is the closest node to the failure node. The failure of advertising destination node will not affect the query result in theory, since it can reach the proxy node. Case 2: The event has already been published in the structure before the failure happens. When a node with event advertisement dies, queries to this node are passed to its parent node. In this case, the event is still reachable unless all the nodes along the querying path were dead. We will further discuss the performance of each case in simulation part.

Load balancing: Static hierarchical configuration and clusterhead election lead to unbalanced energy consumption at various levels. High level nodes are more frequently utilized and prone to depleting. Load balancing can be achieved by shifting the decomposition direction periodically, such that the clusterheads can be rotated at various regions. Instead of choosing the clusterhead toward the center, they can be easily modified to any other directions. In those cases root nodes will be distributed to each geographic corners. DQT pays no extra costs for such alternation since the DQT is maintained as stateless.

VII. SIMULATION

We investigate the performance characteristic of DQT using the ns-2 wireless network simulator. Our simulations mainly focus on two aspects: stretch factor and fault tolerance. 256 nodes are simulated in our experiment, which are uniformly distributed in a 2-dimensional square of 3200x3200. The distance between each node is 200m, while the transmission range is set to be 250m. Therefore the average degree is about 4 in the field except some border nodes. That is, not all the level 1 neighbors are reachable via single hop. The geographic location of each node is available, and is used to construct the DQT structure in initial phase. The height of the DQT tree is 4, with 4 roots at the top level. The cost of querying an event is measured as the number of hops from the querying node to the node that holds an advertisement about the event.

Our experiments focus on node-level behavior instead of mote-level behavior. Recall that each node represents a level 1

box in the map. As a result, a node failure in our experiment means all the motes in an area of the corresponding level 1 box failed.

7.1. Stretch factor in the absence of faults

We have proved in Theorem 4 that the stretch factor in worst case is $2\sqrt{2}$. We calculate the average distance stretch factor through 100 runs of each experiment. In each round, a query/sink node pair is randomly chosen. We use two measurements s and s' , where s is the ratio of the DQT querying cost to the distance between the query and the event node and s' is the ratio of the DQT querying cost to the GPSR cost. The value of s shows the ratio to ideal cost, whereas s' is ratio of routing a message from the querying point to the event. We found the average s is around 0.6 and s' is around 0.5 in the absence of faults. The reason that s is much smaller than $2\sqrt{2}$ is that the worst case scenarios only occupy a small percentage of the total. Our scheme has a considerably smaller stretch factor compared to the DSIB scheme, which has an average value 0.9~1.

Fig.5 illustrates the average stretch factor s and s' , as well as their standard deviations where the event and querying pairs are randomly selected with varied distance between the query node and event node. For nearby pairs, the s and s' tend to be close to 1, since either GPSR or DQT makes little difference. The average stretch factor s decreases with the increase of the distance of query/event pairs. But we also find, that when the distance is close to the diameter of the map (such as to 14/16 etc), s and s' slightly increase again. We call this phenomenon border effect. The reason is that when the pair of nodes approach the borders of the maps, they are less likely to be connected through their common neighbors.

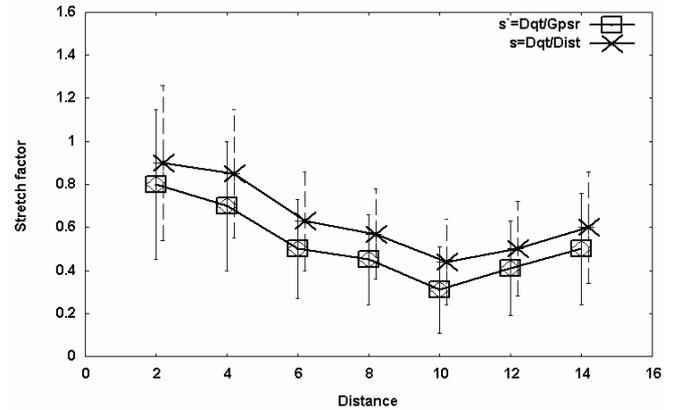

Figure 5: Stretch factor s and s' with varied query distance

7.2 Fault tolerance

DQT is robust in that a single mote failure will not change the structure and the query operation. To evaluate the performance of DQT, node failure in the structure is simulated. We use the same topology and setting in our experiment. We randomly remove a certain percentage of nodes, from 2% to 20%.

We first experiment on the DQT query success rate with node failure. Note that, for case 1, the event still publishes in proxy node when the destination node fails. Theoretically there is no failure for querying, unless GPSR fails to forward along the path or the network is isolated. In case 2, the query is extended to the parent node when a node with event advertisement fails. A query may fail when all event nodes along the querying path fail. Fig.6 shows that for case 1, when query success rate can drop down to 95% when 20% of nodes fail. However, for case2, the DQT scheme itself may fail besides the GPSR routing failure. The failure rate goes up to

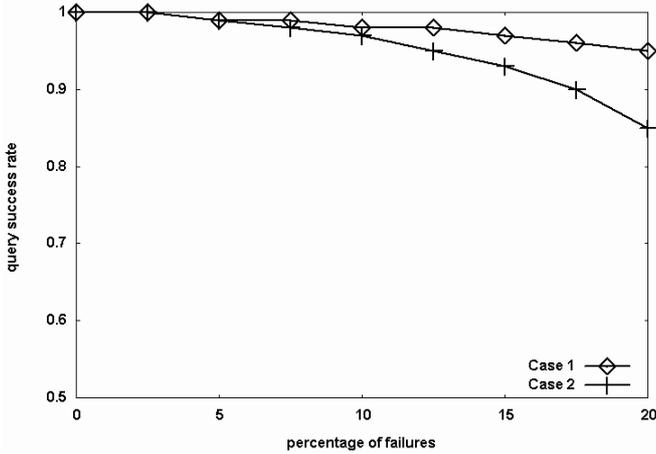

Figure 6: DQT success rate for case 1 and case 2

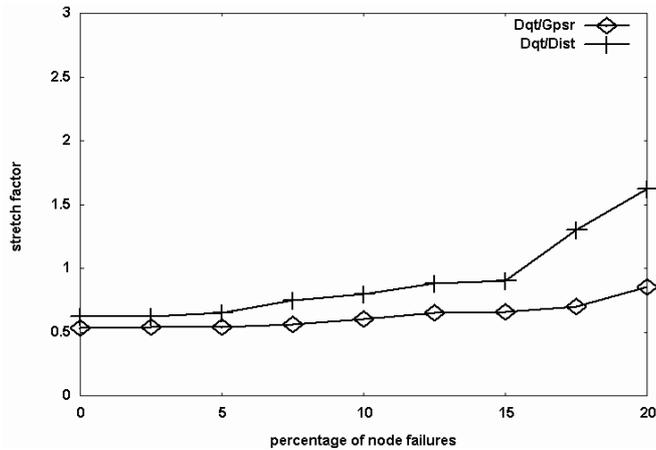

Figure 7: Stretch factor with node failure: Case 1

15% in case 2. The result may vary in real environment due to the increase of GPSR failure and link asymmetry. Increasing the degree of nodes or node density is helpful in improving the query success rate.

From the stretch factor point of view, case 2 is also worse than case 1. Fig.7 and Fig.8 illustrate the stretch factor with varied possibilities of node failure for case 1 and case 2. In both cases, DQT works fairly well within 10% failure of nodes. With the increase in the failure rate, the value s get worse quickly for both cases, because the query circumvents the holes (due to failure), which increases the cost of searching rapidly. Case 1 performs better than case 2 because in the occurrence of

holes, case 2 circumvents the hole and query its parent, while in case 1, the event is achievable through a proxy node. The s' remains relatively small since the same overhead applies for GPSR to overcome the coverage holes. The results also indicate that the degradation of performance is smooth overall.

Finally, for case 2, we plot the trends of s and s' with respect to query distance in Fig.9. Obviously, the failure of nodes affects the overall performance of the DQT. When the failure rate increase, both s and s' will increase for each distance. The s and s' is more closely related in the absence of failure or when the failure rate is small.

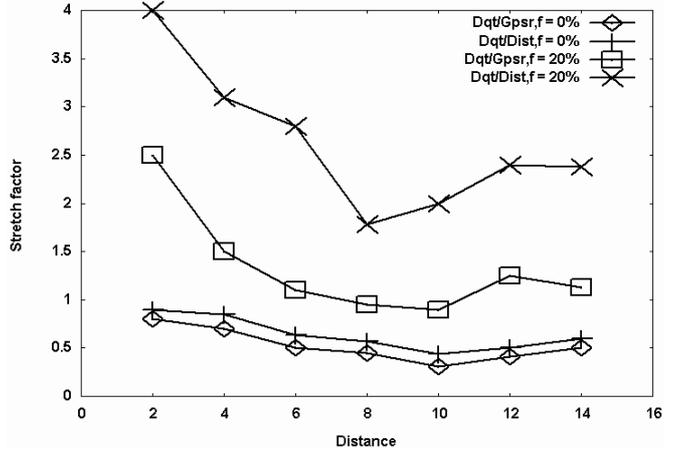

Figure 9: Stretch factor with respect to distance under different failure rate

VIII. CONCLUSION

We presented an in-network querying infrastructure, namely distributed quad-tree (DQT) structure, suitable for use in real world WSN deployments. DQT satisfies distance-sensitive querying as well as efficient information storage in network. DQT construction is local and does not require any communication. Moreover, due to its minimalist infrastructure and stateless nature, DQT shows graceful resilience to the face of node failures.

DQT is amenable to being extended to arbitrary and complex queries rather than the binary version “is there an

event?" queries we presented here. In that case, since the queries are arbitrary, the information advertisement cannot anticipate all queries, and only a summary of sensor data should be stored for energy-efficiency purposes. As such, for resolution of queries there may be several matching options that need to be explored but may not satisfy the query and may result in back-tracking. Model-based query optimization techniques to improve the performance of complex queries are part of our future work.

The stateless nature of DQT makes it resilient to topology changes. In fact, it may be possible to extend DQT to provide a location service for mobile ad hoc networks. The idea is to retry a query until it catches up with the mobile target. Even though a target node may move during the query execution and leads to a miss, the query when invoked from this new location closer to the target node will have a better chance to catch up to the target node due to the distance-sensitivity property in DQT.
