Conditionals and Control Flow

Conditionals in C

We have previously discussed true and false in C:

- 0 is false
- anything else is true

However, boolean expressions and true and false are less unpredictable:

- true and true results are exactly 1
- false and false results are exactly 0
Control Flow

We have discussed only the for loop in C.

Required readings in K&R have covered other control flow.

We will look at if, switch, and their implementations.

There are other control flow statements (discussed in K&R), but they behave similarly to one of these.
Boolean Operators

C uses the following Boolean operators:

- !: Logical not; inverts the following expression
- &&: Logical and; true iff the LHS and RHS are both true
- ||: Logical or; true if either the RHS or LHS is true

Do not confuse these with the similarly-named bitwise operators! (We will discuss those later.)
Boolean Logic in C

C uses a short circuit evaluation for Boolean logic.

This means that evaluation of a Boolean sentence stops as soon as its final truth value is known.

For example:

\[ x \land y \]

If \( x \) is false, then this sentence is false.

In that case, \( y \) will never be evaluated.
Short Circuit Consequences

The consequences of short-circuit evaluation can be surprising. If terms in the sentence have side effects, those side effects may not run.

This can be very useful, but also surprising!

```java
if (i < len && array[i] == SOMEVAL) {
    /* Useful! If array[i] is past the end of the array, the illegal access never happens. */
}
```
Equality Operators

There are two equality operators:

- `==`: Compares value equality, returns true if equal
- `!=`: Compares value equality, returns false if equal

Note that these operators compare values, not logical truth!

In particular, note that many values are “true”, but true is 1!

This means that two logically true values may compare unequal.
Truthiness

```c
bool x = true;
int y = 2;

if (x)
    printf("x is true\n");
if (y)
    printf("y is true\n");
if (x == y)
    printf("x and y are equal\n");
```
### Truthiness

```c
bool x = true;
int y = 2;

if (x)
    printf("x is true\n");
if (y)
    printf("y is true\n");
if (x == y)
    printf("x and y are equal\n");
```

**Output:**

- x is true
- y is true
The header `#include <stdbool.h>` defines some useful things.

- The type `bool`, which holds only 0 or 1
- The values `true` and `false`

Before C99, these things didn’t exist in the standard, but were widely defined in programs.

Therefore they were standardized to require a header.

```c
bool b = 2;
printf("%d\n", b);
```

Output:

```
1
```
Control Flow

Control flow is the path that execution takes through a program.

The C model is linear flow by default.

Control flow statements can change the order of execution.

This is how our programs make decisions.

We will examine how this flow is achieved.
The **if** Statement

The *simplest control statement* in C is **if**.

Its syntax is:

```c
if (condition) {
    body;
}
```

If the expression `condition` evaluates to any true value, `body` runs.
Otherwise, `body` is **skipped**.
Implementing if

The `if` statement must be compiled to machine instructions.

Those machine instructions must encode the condition check and jump.

This is normally implemented as a conditional branch instruction.

You don’t have to learn assembly for this course, but we will look at some machine instruction concepts.
A Simple Condition — C

```c
int main(int argc, char *argv[])
{
    if (argc == 2 && argv[1][0] == '-') {
        puts("negative");
    }
    return 0;
}
```
A Simple Condition — Assembly

```assembly
    cmpl $2, %edi ; compare argc to 2
    je .L8 ; jump to .L8 if ==
    .L4:
    xorl %eax, %eax ; set up return value
    ret ; return 0
    .L8:
    movq 8(%rsi), %rax ; load argv[2][0] into %rax
    cmpb $45, (%rax) ; compare %rax to 45 ('-')
    jne .L4 ; jump to .L4 if !=
    leaq .LC0(%rip), %rdi ; load "negative" into %rdi
    subq $8, %rsp ; make room on stack
    call puts@PLT ; call puts("negative")
```

Conditional Instruction Flow

Note that the structure of the program was lost.

One of the advantages of high-level languages is structure.

The computer can generally only:

- Make simple comparisons (sometimes only to zero!)
- Jump to a program location

Anything more complicated is a software construction.
The `else` Clause

The `else` clause is simply either:

- The `next instruction` after a jump
- The `jump destination` (with the `if` body being the next instruction)

Which layout the compiler uses depends on the code and architecture.
else Gotchas

I have previously advocated *always using blocks*.

Here is a place where it really matters:

```c
if (modify_x)
    if (negate)
        x = x * -1;
else
    y = -x;
```
else Gotchas

I have previously advocated *always using blocks*.

What this *actually means* is:

```c
if (modify_x)
    if (negate)
        x = x * -1;
    else
        y = -x;
```
else Gotchas

I have previously advocated *always using blocks*.

What you *should use* is:

```java
if (modify_x) {
    if (negate) {
        x = x * -1;
    }
} else {
    y = -x;
}
```
Understanding `else if`

Unlike some languages, C does not have an `else if` statement. Instead, it uses `else if`.

This is because `if` is a statement that forms the else body.

Therefore, `else if (...)` is actually `else { if (...)}`!

Languages using `elif`, `elsif`, *etc.* often have syntax reasons. Consider Python:

- `else if` is missing:
- `else: if` has invalid indentation.
The `switch` Statement

C provides a convenient multi-case condition statement: `switch`.

It compares an integer with a set of values.

The first matching integer value begins execution.

```
switch (integer) {
case value1:
    body_for_value1;
    break;

case value2:
    body_for_value2;
    break;

default:
    else_body;
}
```
### switch Gotchas

The `break` keyword is never implied.
**switch Gotchas**

The **break** keyword is never implied.

```c
int i = 42, value = 17;
switch (value) {
    case 17:
        i ++;
    case 12:
        i ++;
    default:
        i ++;
}
printf("%d\n", i);
```

Output: 45
switch Gotchas

The break keyword is never implied.

```c
int i = 42, value = 17;
switch (value) {
    case 17:
        i ++;
    case 12:
        i ++;
    default:
        i ++;
}
printf("%d\n", i);
Output:
45
```
